These essays are illustrated and very neatly published. They have the advantage over isolated journal reports of being surveyed by comparison, being "co-ordinately and coherently" published, as the author well puts it. They surely make valuable additions to neurological literature.

Bulletin of the Harvard Medical Alumni Association-Number 14 Catalogue. Boston: Published by the Asso, ciation. 1900.

A valuable feature is the list of members by States and Territories. Of course, Massachusetts has the most, but New York is well represented. Alabama heads the list with one member.

Die Krankheiten der Frauen. Von Dr. Med. Heinrich Fritsch. Neunte Auflage. 1900.

This is the ninth edition of the well-known text-book on gynæcology much used in Germany. It is a clear and thorough exposition, well adapted and suitably illustrated, and has a fine external appearance. The things which are required of a text-book of this kind characterize the work before us. Conforming to the rapid progress of medical science in the gynæcological field, the present edition of the book has been changed in many respects, and many new things have been added. Special mention must be made of the first chapter, in which the author discusses asepsis and antisepsis in gynæcology, describing all the necessary measures and steps before the operation; the preparation of patient, instruments, and the surgeon himself. Attention is also directed to the last chapter, which is entirely new—the treatment of the patient after a laparotomy and complications following it. The book is well known from its previous editions and is worthy of full recommendation.

The Transactions of the Medical Society of the State of California, thirteenth annual session, San Francisco, April, 1900. Vol. 30. Published by the Society.

The address of the president, George Chismore, is accompanied by his portrait as frontispece. There are many excellent papers on very practical subjects, and the volume is put out in such a way as to reflect decided credit on all concerned.

Thomas Sydenham. By Joseph Frank Payne, M.D., Oxon., Fellow and Harveian Librarian of the Royal College of Physicians, Late Fellow of Magdalen College, Oxford. New York: Longmans, Green & Co. 1900.

This is the eighth volume of the series of "Masters of Medicine," and sustains the high level which its predecessors attained. The author has availed himself of much material which has been hitherto unpublished and gives a most interesting account not only of Sydenham but of his friends and environment as well.

A Guide to the Instruments and Appliances Required in Operations. By A. W. Mayo Robson, F.R.C.S., Senior Surgeon to the Leeds General Infirmary, Hon. Consulting Surgeon to the Keighley and Batley Hospitals, Emeritus Professor of Surgery in the Yorkshire College of the Victoria University, Member of Council and Hunterian Professor R.C.S. of Eng. Second edition. Sixty-two pages. Two shillings and sixpence. London, Paris, New York, and Melbourne: Cassell & Company, Limited. 1900.

The author has issued in book form the lists which he uses in his private practice to be followed by his assistants. Realizing that operators require different instruments for their different methods, he has left space at the end of each list which can be filled by those using it. The volume is issued in very compact form and can be readily carried about.

The Physician's Visiting List for 1901. Fiftieth Year of its Publication. Philadelphia: P. Blakiston's Son & Company.

The publishers point with pardonable pride to the fact that this little book has appeared regularly for the past fifty years, and that its survival for so long a period indicates that it has served and will continue to serve a useful purpose. It is compact and is published with or without dates, for twenty-five to one hundred patients a week. There are spaces reserved for visiting list, memoranda, addresses, accounts, obstetric engagements, vaccinations, and deaths, besides the usual printed tables and other useful data.

Food for the Sick and How to Prepare it. With a Chapter on Food for the Baby. By Edwin Charles French, M.D. One hundred and seventy pages. Louisville: John P. Morton & Co. 1900.

This book makes a very helpful work to the busy practitioner. Quite a number of diseases are treated from a dietetic standpoint, and a full list of foods appropriate for each is given. A number of valuable recipes for the preparation of invalids' food, not ordinarily found in cook books, takes up the larger part of the book. The article on rectal alimentation, although short, will prove of value to the reader.

Ueber die Behandlung der Kinderkrankheiten. Briefe an einen jungen Arzt. Von Dr. Hugo Neumann, Privat-Docent an der Universität in Berlin. Zweite, durchgesehene und erweiterte Auflage. Berlin: Oscar Coblentz. 1900.

The second edition of this instructive book, comprising about three hundred and seventy-three pages, is a unique work in that it appears in a series of letters giving careful attention to the therapeutic and dietetic management of the most important infantile disorders. The author gives particular attention to infectious diseases, and his clearness of description deserves especial mention. To the physi-

cian desiring detailed information in the treatment of diseases of children this book can be recommended. A medical formulary, giving a series of recipes with the dosage of drugs, is appended. Dr. Neumann being the director of the Poliklinik in Berlin, his views embody a large personal experience, which greatly enhances the value of his work.

Disinfection and Disinfectants. A Treatise upon the Best-known Disinfectants, their Use in the Destruction of Disease Germs, with Special Instruction for their Application in the Commonly Recognized Infectious and Contagious Diseases. By H. M. Bracken, M.D., Professor of Materia Medica and Therapeutics, University of Minnesota; Secretary and Executive Officer, Minnesota State Board of Health. Eighty-five pages. Chicago, Ill. Published by The Trade Periodical Company. 1900.

This little book affords the reader a concise and practical description of the different methods of disinfection now in vogue. The relative efficiency of the different chemicals, heat, sunlight, etc., are discussed and the methods of using the formaldehyde apparatuses are clearly and succinctly described. How the disinfector should dress and act, and what precautions should be taken for the special diseases, both in regard to the patient and the attendant, are all treated in a satisfactory and practical manner.

Practical Homœopathic Therapeutics. Arranged and Compiled by W. A. Dewey, M.D., Professor of Materia Medica in the University of Michigan Homœopathic Medical College; Member of American Institute of Homœopathy; Corresponding Member of the British Homœopathic Medical Society and of the Société Française d'Homœopathie; Author of "Essentials of Homœopathic Materia Medica," "Essentials of Homœopathic Therapeutics," etc. Philadelphia: Boericke & Tafel. 1901.

This volume serves to indicate how closely the two schools of medicine have agreed on the remedies which are useful in different diseases. Thus, under anæmia, we find iron, arsenic, and cinchona as leading remedies; under angina pectoris, amyl nitrite and glonoin; under arthritis, colchicum, etc. Of course, the drugs peculiar to homœopathy are also included under the different headings, which are arranged alphabetically, whether as symptoms or as definite diseases.

Psychopathia Sexualis, with Especial Reference to Antipathic Sexual Instinct: A Medico-Forensic Study. By Dr. R. v. Krafft-Ebing. The only authorized English translation of the tenth German edition. Chicago W. T. Keener & Co. 1900.

In the publishers' preface we read that the sale of this work is rigidly restricted to the members of the medical and legal professions. The first edition appeared some time previous to 1892, when the first American translation was published by the F. A. Davis Company. In the preface to the tenth edition, which was written in 1899, the author says the commercial success of the work is the best proof that large numbers of unfortunate people find in its pages instruction and relief in the frequently enigmatical manifestations of sexual life. Undoubtedly the work has drawn a very large list of readers from every walk of life outside of the professions to which the sale is so rigidly restricted. The present book is somewhat larger than former editions, and contains over twenty more case histories with comments than did the ninth. The work is very full and the language scientific. It has undoubtedly done much to bring about a better understanding of the morbid states with which the pages are so pregnant, but in improper hands such works are capable of sowing harmful seed.

The Treatment of Fractures of the Patella.—A. Wiener describes a method of treating this fracture which produces good functional results without operative interference. The leg is shaved and sterilized as for operation and enveloped in non-absorbent cotton. It is then placed on a gutter splint of binders' board, and after plentiful padding the knee joint is surrounded by figure-of-eight turns of a broad rubber bandage, drawn moderately tight. An ambulatory apparatus is applied, and the patient allowed to walk home. The rubber bandage is allowed to remain in place four or five days, at the end of which time the exudate will be found to have become greatly diminished, so that the bone fragments can easily be placed and retained in apposition by a reapplication of the dressing.—*Centralblatt f. Chirurgie*, January 5, 1901.

Therapeutic Hints.

Treatment of Paralysis Agitans.—We seem to be unable to stay these subtle changes which are taking place in the nervous system. The rigidity and soreness, painful condition of the muscles, which even sometimes precede the development of tremor, progressively advance. The tremor, weakness, and final rigidity we are unable to prevent. Every day brings these patients that much nearer a horrible end—paralysis, rigidity, and complete hopelessness. — Dr. Charles J. Aldrich, *Bulletin of the Cleveland General Hospital.*

Uræmia and Uræmic Convulsions.—In uræmia and uræmic convulsions we have the right to use the more powerful drugs, which we should always fear to employ in the milder conditions. Croton oil, elaterium, muriate of pilocarpine, jaborandi, by enema or supositories, atropine, and strychnine in œdema of the lungs, chloral hydrate, chloroform, and even morphine in convulsions. Morphine should never be used except in the worst and most violent stages of the convulsions of acute nephritis.—Dr. L. G. Le Beuf, *Medical and Surgical Journal*, December.

Acute Laryngeal Inflammation.—

℞ Menthol ..... gr v
(or chloroform ..... gtt. i)
Tr. opii camphorat ..... ʒ ss
Tr. benzoini comp ..... q s ad ʒ ij
M. S. One teaspoonful in a pint of hot water, for inhalation.

—Musson.

Specific Urethritis.—To render the urine aseptic.

℞ Salol ..... ʒ i
Boric acid ..... ʒ i
M. Div. in capsulas No. xii. S. One four times a day

To render the urine alkaline, alkaline waters may be given freely, or

℞ Potass. bicarb ..... ʒ iij
Tinct. hyoscyam ..... ʒ ij
Aquæ ..... ad ʒ iv
M. S. A teaspoonful in water after meals.

Or:

℞ Ext. pichi fl ..... ʒ iij.
Potass acetat ..... ʒ i
Spts. æther. nitros ..... ʒ ij.
Syr. simplicis ..... ʒ ij.
Aquæ ..... ad ʒ viij.
M. S. A teaspoonful in water after meals.

Injections should not be used until the acute symptoms begin to subside. Hot boric-acid solution may be used first. These are useful:

℞ Zinc. sulph ..... gr. vi.
Ext. hydrastis fl..
Glycerin ..... āā ʒ iv
Aquæ ..... ad ʒ vi.
M.

Or:

℞ Protargol ..... gr xxv.
Aquæ ..... ʒ vi
M.

Dr. W. A. Hackett, *The Medical Age*, November 25th.

Treatment of Corns.—For the soft corn between the toes, ordinarily, gently greasing the toes well in the morning with some simple ointment and putting a film of cotton between will in a few days cause them to disappear. When there is much moisture a powder of salicylic acid, or resorcin, or thuja in five-per-cent. strength, mixed with compound stearate of zinc, may be used instead of ointment. Rhubarb powder, in twenty-per-cent. strength with arrowroot powder, does

well also. For the flat corn, not especially painful, the salicylic-acid plaster (ten per cent.) is useful.—Dr. Isadore Dyer, *New Orleans Medical and Surgical Journal*, December.

Cancer of the Uterus.—

℞ Iodi. . . . . ʒ i.
Bromi . . . . . ʒ ij.
Acid carbol . . . . . ʒ iv
Alcoholis . . . . . ʒ viij
M. S. Apply and then introduce a saturated solution of bicarbonate of sodium.

—Parvin.

Epilepsy.—

℞ Tinct. belladonnæ . . . . . ♏ ij.
Potass. bromidi . . . . . gr xv.
Chloral hydrat . . . . . gr v
Aquæ . . . . . q.s ad ʒ i.
M. S. For one dose.

—Starr.

Painful Erections.—

℞ Methyl salicylate . . . . . 1 part.
Liquid vaseline . . . . . 10 parts.
M. S. Anoint the penis with this liniment and cover with a thin layer of cotton and bandage.

—Bavatier.

Pruritus Vulvæ.—

℞ Bichloride of mercury . . . . . gr. ss.
Emulsion of bitter almonds . . . . . ʒ i.
Apply twice a day.

Or:

℞ Tr opii,
Tr. iodi,
Tr aconiti . . . . . āā ʒ v.
Acid carbolic . . . . . ʒ i.
Apply twice a day.

—Penrose.

Gastric Fever in Children.—For the head symptoms accompanied with high fever, I apply the ice bag to the head, and give internally:

℞ Tinct. aconiti rad . . . . . ♏ xxx.
Tinct. gelsemii . . . . . ʒ i.
Syr. ipecac . . . . . ʒ iij.
Aq cinnamomi . . . . . q.s. ad ʒ i.
M. S. Fifteen drops every hour till the fever is reduced, then every two or three hours. For a child six years old.

Many children cry distressingly of the pain in the stomach; for this I have found the following mixture useful:

℞ Spts chloroformi . . . . . ʒ i.
Bismuthi subnit . . . . . ʒ iss.
Morph. sulph . . . . . gr. i.
Elix lactopeptin . . . . . ʒ i.
Aq menth. pip . . . . . q s ad ʒ ij.
M S. Half a teaspoonful every half-hour till relieved, then every three hours.

After the high temperature is under control, and to remove the disagreeable taste in the mouth, along with the fetor of the breath, and also act as a systemic tonic, I administer:

℞ Tinct. ferri chlor.
Acid phos. dil . . . . . āā ʒ ij.
Syr. limonis . . . . . q.s. ad ʒ ij.
M. S. Half a teaspoonful, given in a small wineglass of water, three times a day. To be continued for ten days.

—Dr. G. T. McCullough, *Denver Medical Times*, November, 1900.

The Treatment of Typhoid Fever.—I have found it impossible to bathe certain patients because the plunges have led to hysterical or nervous outbreaks that seemed to me more dangerous than the conditions that the cold baths might obviate; it has been impossible to bathe certain patients because of direct objections on the part of the friends; and I have sometimes discontinued the baths when the shivering and nervousness have been extreme, and it has seemed too much of a hardship to the patient to continue. These contraindications to bathing are not usually admitted by enthusiasts, but in practical medicine physicians will find that these objections to the bath will have weight with them. I do not specify these, nor should they be used as cloaks to hide a real objection to cold bathing which we are unwilling to confess, but, on the other hand, the ardent advocates of bathing recognize that their advocacy of invariable plunging sometimes carries them to the point of cruelty. As between the danger of death and certain grades of suffering, intelligent persons will often select the former This privilege must be allowed the typhoid patient.—Dr. Alfred Stengel, *Pennsylvania Medical Journal*, November.

Aqueous Extract of Suprarenal Glands.—I have used it with excellent results in the treatment of oncoming and existing tonsillitis in all four tonsils, from the simplest congestion to the most severe quinsy, and even in diphtheria. The spraying of the suprarenal upon the congested and swollen tissues not only reduces the congestion for the time being, but causes the whole organ to seem to the patients less swollen. They speak immediately of increase of space in the throat, and are able, especially in the severe quinsy cases in conjunction with a little cocaine, to get down some sadly needed nourishment.—Dr. Henry L. Swain, *Yale Medical Journal*, November, 1900.

Surgical Suggestions.

Appendicitis.—As far as our present knowledge extends, the appendix vermiformis in the human being is rudimentary and functionless, and therefore of no possible use or benefit to man. At any rate he seems to get along as well or better without it than he does with it. An operation for appendicitis is performed in all cases for two reasons—first, to save the life of the patient, and secondly, to remove the cause of the disease. These requirements will not be accomplished unless the appendix is removed in every case. It is bad and imperfect surgery to leave after an operation the cause of the trouble.—James B. Morgan, M.D., *International Journal of Surgery*, October.

Hydrogen Dioxide in Appendicitis.—In a case of appendicitis with abscess, hydrogen peroxide is a sheet anchor. Armed with this resource, one may without hesitation open pus collections freely, separate peritoneal adhesions without regard to exposing the general peritoneal cavity to infection, and in short, he can work in violently infected cases without fear of lighting up general peritonitis. As soon as pus appears proceed to blow it all out of the cavity by introducing hydrogen dioxide in sufficient quantity to accomplish that purpose. Separate adhesions and search for further pus collections and the infected appendix. If pus appears repeat the same procedure.—Robert T. Morris.

Wrist-Drop due to Traumatism to the Musculo-Spiral Nerve.—The result of secondary neurorrhaphy is frequently not very good. This is due to carelessness in after-treatment, little or no treatment is carried out, and unless persistent massage, douching, and electrical treatment are systematically performed for at least a year, we can scarcely expect any good result. Simple suture of the nerve, leaving the muscles wasted from prolonged disuse, will of itself do but little good. The methods I have resorted to are (1) simple suture after stretching, (2) stretching and bridging the still existing gap in the nerve with strands of catgut, and

(3) deliberate resection of the shaft of the humerus. The latter has given the best results.—W. W. KEEN.

Fractures in the Neighborhood of or into a Joint.—When a fracture is in the immediate neighborhood of or into the joint itself, there certainly will be a traumatic inflammation of that joint, which demands consideration as well as the fracture. My judgment and experience tell me that the best method to pursue is to appose the fragments as completely and thoroughly as possible, place the joint in that position which will best maintain that apposition with safety to the part and comfort to the patient, then immobilize the joint and fragments by a suitable dressing until firm union of the fragments occurs, followed then by very judiciously practised passive motion of the joint. The best treatment for an inflamed joint, pure and simple, is rest; why, then, would not this treatment be just as reasonable when the inflammation is associated with a fracture?—DR. ROBERT CAROTHERS, *Cincinnati Lancet-Clinic*, December 8th.

Diagnostic Differences in Three Forms of Intestinal Obstruction.—

STRANGULATION BY BANDS.	VOLVULUS.	INTUSSUSCEPTION.
	Age.	
Young males.	Males about forty.	Young children.
	Pain.	
At umbilicus; severe from beginning.	Hypogastrium or back; comes on at once, but not so severe; intermits.	Prominent; comes in waves.
	Vomiting.	
Early, frequent, copious, stercoraceous, fourth or fifth day.	Late or not at all; never very urgent; fifteen per cent. of all cases feculent.	Very variable symptoms.
	Constipation.	
Complete from first.	From first.	Blood from bowels with tenesmus.
	Abdominal Distention.	
Not at first marked; no tumor.	Rapid accumulation of gas, causing great distention; no tumor.	Usually absent; tumor felt through parietes or in rectum.
	Duration.	
Die about fifth day.	Average six days.	Twenty-four hours to several days or weeks.

—DR. J. W. MACDONALD.

Carcinoma.—The use of caustics in the radical treatment of carcinoma has a limited field of usefulness.—SENN.

Cutaneous cancers are usually treated more satisfactorily by escharotics than by any other method.—DANIEL LEWIS.

Caustic agents should be applied in such a manner as to produce the requisite effects by single application, otherwise the irritation gives not necessarily, but commonly, new activity to the disease.—WALSHE.

The caustic which has given me the best results is what is known as Bougard's caustic compound, and it is as follows:

℞ Wheat flour	60 gm.
Starch	60 "
Arsenic	1 "
Cinnabar	5 "
Sal ammoniac	5 "
Corrosive sublimate	0.50 cgm.
Solution of chloride of zinc at 52°	245 gm.

—DR. S. B. M'GAVRAN, *Columbus Medical Journal*, November.

Continuous Dilatation in Urethral Stricture.—Continuous dilatation is employed under the following conditions: (1) When we fail to make progress with "interrupted" dilatation. (2) When speedy relief is required owing to the occupation of the patient. (3) When, owing to cystitis existing as a complication, continuous drainage through a catheter is required. (4) When, through age or debility, and particularly when disease of the kidneys is known or suspected to exist, an operation is inadmissible. (5) In tight strictures, and such as involve difficulty in introducing instruments, it will almost invariably be necessary to commence treatment by continuous dilatation, and when sufficient progress has been made to permit of the easy introduction of bougies, to continue the treatment by "interrupted" dilatation. (6) Continuous dilatation has almost invariably to be employed as a preliminary to internal urethrotomy. In most cases as soon as we have dilated a stricture up to 16 or 17 F. (9 E.) by the "continuous" method, the treatment should be completed by the passage of large steel dilators by the "interrupted" method.—DR. P. J. FREYER, *The Clinical Journal*, December 5th.

Society Reports.

THIRD PAN-AMERICAN MEDICAL CONGRESS.

(*By cable to the* MEDICAL RECORD.)

FIRST GENERAL SESSION.

THIS was held in Tacon Theatre on Monday evening, February 4th. The house was filled with representatives of Havana society and on the stage were officers of the congress, national delegates and vice-presidents, Mayor Rodriguez of Havana, and other officials.

Address of Welcome.—The congress was opened by GOVERNOR WOOD with a brief address. He said that upon him was placed the agreeable duty of opening the congress and welcoming its members to Cuba. The selection of Havana as the place of meeting was peculiarly opportune, as it was the capital of an island lying midway between the two continents and representing the bond of union between them. Moreover, it was easy of access from north and south, and visitors would have an opportunity to study and discuss the results of work done in the past six months—work tending to the solution of the yellow-fever problem. He was privileged to welcome his hearers as strangers in the hospitals of Havana, and especially as members of the great brotherhood of scientific men, as seekers after truth, knowing no difference of race, no national prejudice or antipathies.

Report of the Secretary-General.—DR. CORONADA then read his report, giving the history of the organization of the present congress. The disturbed state of Venezuela forbade the assembling of the congress in Caracas, and almost at the last minute Havana was asked to receive it. At a meeting of physicians it was unanimously decided to comply with the request, and invitations were sent to all American countries and accepted officially by most of them. The prevalence of yellow fever necessitated the postponement of the date. In consideration of all these facts the delegates should overlook any shortcomings. In the name of Cuba he bade the visitors welcome.

The President's Address.—DR. JUAN SANTOS FERNANDEZ welcomed the members of the congress in a brief address in which he reviewed the medical history of Cuba. Of all the countries which formed the vast colonial possessions of Spain none excelled Cuba in her love of medical sciences. Her first hospital was erected in 1546. In 1728 the Dominican Friars established a university in which was a faculty of medicine. From this school, despite many impediments, came men still remembered for their medical acumen. The most illustrious of Cuban physicians in the eighteenth century was Romay, who established the first Cuban medical periodical and published an interesting memoir on yellow fever, as well as several

works on hygiene. He introduced vaccination in Havana in 1804, disarming the popular prejudice by first vaccinating his own children. During the visitation of the cholera in 1833, the Cuban physician Calcagno called attention to the premonitory diarrhœa, during which proper treatment might arrest the disease. Gutierrez was the successor of Romay in knowledge of the sanitary requirements. He gave a new impulse to medical learning, established the Academy of Sciences of Havana, and was the editor of the first medical journal published in Cuba. The speaker then referred to the state of medical literature in the island, to the work of the Cuban medical congress in 1890, and to that of various local scientific associations. He contended that Pasteur's discoveries were accepted in Cuba before they were recognized by any other country. As evidence of this fact the Institute of Bacteriology and Antirabic Inoculation was established in Havana in 1887 and still existed. In closing Dr. Fernandez predicted a glorious medical future for Cuba, now recovering from losses of blood and treasure spent in her struggle for freedom.

The address which was to have been delivered by Colonel Reed, of Cincinnati, was omitted because of the absence of the author.

Progress of Obstetrics.—Dr. Hernandez, of Havana, delivered the address on the progress of obstetrics. The selection of the theme was unfortunate in view of the mixed character of the audience, as was evidenced by attempts of the spekaer to veil the meaning of terms by using that of mannikin instead of female, and by rather clumsily avoiding necessary references to strictly scientfiic facts. He discussed the position the fœtus assumed in consequence of fixed anatomical conditions, the phenomena of normal delivery, the use of the forceps, the indications for symphyseotomy and antisepsis, and spoke of many illustrious names (some Cuban) which were associated with the advances in the art and science of obstetrics, claiming that they should be known and reverenced by the laity as well as by the profession for the part they had taken in advancing this important department of science and the consequent saving of human life.

SECOND GENERAL SESSION.

Held in Marti Theatre, Tuesday Evening, Feb. 5th.

The Progress of Medicine in Cuba was the theme of the first address, which was delivered by Dr. Gustavo Lopez, the vice-president of the congress. The speaker sketched in a few words the history of medicine in Cuba. He was proud to say that his medical brethren were always alert to adopt new ideas when they were proved to be sound and to turn to practical use all strictly scientific discoveries. Bacteriology especially had been always zealously pursued in Cuba, Pasteur's teachings having been early adopted and put to practical tests. He referred to the successful meeting of Cuban physicians in 1890. The disturbed condition of the island alone prevented subsequent gatherings.

A Pan-American Yellow-Fever Congress.—Dr. Eduardo Wilde, Argentine Minister to the United States, followed with an address advocating the united action of all American governments looking to the extermination of yellow fever. He declared emphatically that this disease gained no foothold where hygiene was perfect, and experience had abundantly demonstrated that places hitherto infected could be freed from the scourge of fever by the amelioration of existing sanitary conditions. In conclusion the speaker offered a resolution for adoption calling upon all American governments to appoint delegates to meet in Pan-American congress to determine measures necessary for the extinction of yellow fever in its endemic foci. He maintained that each port should be subjected to sanitary survey and any needed improvements should be specified for each place. These works should be carried out under direction of a Pan-American commission, and each government should bind itself to execute the sanitary improvements declared necessary. Whatever the actual cost of such work might be, its execution would in the end be economical, in view of the immense losses to commerce and human life resulting from an outbreak of yellow fever. He stated that he had proposed to Surgeon-General Wyman to request the respective governments to convene a sanitary congress, as above outlined, but when the call for the present meeting was received it was deemed best to lay the project before the congress and let such a proposal come in a more direct way to the respective governments, backed as it would be by high scientific sanction.

Progress of Medical Science.—Dr. Luis Debayle, delegate from Nicaragua and Honduras, then spoke on this theme. He sketched briefly the condition of medicine up to the close of the eighteenth century and showed the radical changes which had been due to the work of Pinel, who first directed scientific inquiry in the path of exact science. He referred to the creation of general anatomy by Bichat and to progress in histology, embryology, and experimental physiology due to the cellular theory of Virchow; also to various other discoveries up to those of Broca, Waldeyer, and Ramon y Cajal. He spoke of the chemistry of cells and declared chemistry to be the science of the future. He referred to Gautier's theory of toxins and sketched the progress of clinical medicine associated with the discoveries of Laennec, Trousseau, Bright, Rokitansky, and others; and also alluded to the influences of thermometry, laryngoscopy, cystoscopy, and the Roentgen ray in surgery, and spoke also of anæsthesia, antisepsis, and forcipressure. The greatest triumphs of modern surgery were those of anæsthesia and asepsis. Equally brilliant discoveries were awaiting the developments of bacteriology. The demonstrations of Pasteur were merely the beginnings of what was to be. Orrhotherapy would yet assert itself as a leading system of treatment for infectious diseases and he doubted not that many of his hearers would live to see the most extravagant prophecies in such directions fully verified.

Defence against Tuberculosis.—This was title of an address by Eduardo Liceaga, of Mexico, which was read in his absence by another. He reviewed the modern doctrine concerning tuberculosis, that it was a contagious but preventable disease. The germ issued from the tuberculous individual in the sputum, fæces, urine, purulent discharges, and gained admission to the healthy organism through the respiratory and digestive tracts, and through wounds. Experience had demonstrated that in proportion as the sanitary condition of cities improved tuberculosis diminished. Not the least of advantages of sanatoria were that they were schools of hygiene for consumptives, and taught patients not only to care for themselves but to protect their neighbors from infection. He referred to the measures necessary to prevent the spread of the disease, especially isolation, disinfection, and early diagnosis. He contended that there should be notification of all cases to the health authorities, and urged a crusade against tuberculosis by the organization of vast associations similar to those of the Red Cross. Physicians should take the initiative in furthering the good cause by precept and example.

The attendance at the congress was about four hundred, of which one hundred members were from the United States, and seventy-five from other countries.

(*To be Continued.*)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 28, 1901.

GEORGE B. FOWLER, M.D., PRESIDENT.

Modern Views of the Pathology of Diabetes.—DR. C. A. HERTER read this paper, treating particularly of certain aspects of the disease to which he had given special attention. He considered that the presence of sugar and that of organic acids in the urine were the two characteristics of this disease. Our knowledge of the causes of glycosuria had been considerably augmented of late by a variety of experiments. One view regarding the cause of sugar in the urine was, that it was owing to injury to the kidney, thus permitting the sugar to escape into the urine in very much the same way that albumin escaped into the urine, when the kidney had been injured by a nephritic process. The chief argument in support of this view was that derived from a study of phloridzin diabetes. Phloridzin was a glucoside obtained from the cherry, apple, and some other vegetable sources. If half a gram or more of phloridzin be introduced in alkaline solution under the skin of a dog, the urine would be found to contain a very considerable quantity of sugar, and this continued until the organism began to break down its own proteid. One investigator had found that if a solution of phloridzin were injected directly into the renal artery on one side, sugar appeared in the urine on the side on which the injection had been made, some time before it appeared from the other kidney. It had been inferred from this that the kidney had been injured first on one side, and then on the other. The idea that the sugar passed into the urine on account of injury to the kidney had received support from observations made on the sugar content of the blood before and after the injection of phloridzin. It was claimed that the quantity of sugar in the blood was less after than before the administration of phloridzin. His own experiments confirmed this view, indicating that there was a sweeping out of the sugar from the organism. It had been formerly supposed, probably as a result of Claude Bernard's observations chiefly, that the sugar content was uniformly increased. In severe cases of diabetes, however, the sugar in the blood was distinctly increased above the normal, and this seemed to be an objection to the view that injury to the kidney was the cause ot human diabetes. The problem had been very much complicated by the fact that the blood contained some substances which reduced Fehling's solution, but which were not sugar. For instance, Drexel had shown about ten years ago that the blood contained a substance known as jecorin, which was a combination of lecithin and sugar. There was reason to believe that the presence of lecithin sugar accounted for the reaction ordinarily obtained with Fehling's solution, and that there was no sugar in the blood normally. It was only when sugar came into the blood in addition to the jecorin that sugar was found in the urine. There was no good evidence that there was ever an increased production of sugar in the blood, either from carbohydrates or from proteids, and usually not from fats. In cases of diabetes, before that condition led to coma, the sugar in the urine could not be explained on the supposition that there was an increased production of sugar in the organism. The alternative theory was that there was a decreased combustion of sugar—a view which was supported by the best physiologists, and was apparently the only really tenable theory. The sugar was stored in the form of glycogen in the liver and, to a less extent, in the muscles. It had long been known that injury to the floor of the fourth ventricle was apt to be followed by the appearance of sugar in the urine, and that this did not happen if there was no glycogen in the liver and muscles. The glycogen could be removed from these tissues by starvation or by the administration of jecorin. The explanation of these observations, the speaker thought, was to be found in the changes in the circulation of the liver—the increased flow of blood brought about by the vasomotor changes. As a rule, the diabetes following an injury to the head in the human subject was of short duration, but permanent and even severe glycosuria from such injury was not unknown. Under such circumstances it must be assumed either that the pancreas was also involved, or that the circulation in the liver had been permanently changed in such a way that no carbohydrate could be stored as under normal conditions. Another explanation of the inability of the body to burn its sugar was to be found in defective oxidation in the cells, and possibly also to some extent in the blood, but it was evident from certain experimental facts that this could hardly be the primary difficulty in the case of diabetes, for there were conditions in which the oxidative capacity of the cells was markedly diminished, *e.g.*, acute yellow atrophy of the liver or acute phosphorus poisoning, and yet diabetes did not occur. Probably the primary difficulty was to be found in the inability of the organism to cleave the sugar molecul in such a way that it could be converted by oxidation into carbon dioxide and water. It was now believed that a ferment produced somewhere in the organism was the means by which this sugar-splitting process took place. It was well known that the complete removal of the pancreas was uniformly followed by the appearance of sugar in the urine. It had been shown repeatedly that the pancreatic duct could be ligated, and still no diabetes would result. The speaker said that in his somewhat limited experience in post-mortem examinations of cases of diabetes, there had not been a single case in which the pancreas had not been extensively diseased. Reference was made to the histology of the pancreas, and particularly to the islands of Langerhans as showing the admirable arrangement for the intimate interchange of material between the cells in this structure and the blood. The next point brought out was that there were two forms of pancreatitis, viz., (1) one in which there was an extensive increase of the connective tissue without much involvement of the glandular substance, and (2) one in which the connective tissue was not interlobular, but passed in among the secreting structures and compressed the islands of Langerhans. Diabetes was found associated with this second form of disease of the pancreas. Probably these islands of Langerhans produced an internal secretion which was of use in the combustion of the sugar; the withdrawal of this secretion resulted in an inability of the cells to burn the sugar. Recent observation had shown that in normal persons the blood was capable of destroying a considerable quantity of sugar. In diabetics there was an enormous falling off in the ability of the blood to decompose the sugar. The appearance of sugar in the urine, therefore, was due to diminished combustion of sugar, and this diminished combustion was closely related to disease of the islands of Langerhans, in the great majority of cases. The chief symptoms of diabetes were, of course, readily explained by the deprivation of the system of sugar.

Excretion of Acids in Diabetes.—The excretion of acids in diabetes, the speaker said, was of great importance, and was of more prognostic significance, in his opinion, than the excretion of sugar. With a given quantity of sugar in the urine there might be almost no organic acid in the urine or a very considerable quantity, yet in the one case the prognosis was good, and in the other it was bad. There was little reason to believe that the acids were produced in the

digestive tract in sufficient quantity to account for these acids found in the urine. An explanation was to be found in the fact that something was produced in the organism which was not properly burned. The importance of these acids lay largely in the fact that a free acid appearing in a cell or in the blood could not possibly remain there as a free acid; it must be neutralized by an alkali present in the body. If there was sufficient alkali for this purpose, no evil effect from the presence of the acid would be observed, so long as the alkalinity of the blood was not greatly reduced. The point of danger in the presence of organic acids in the blood and in the urine lay in the fact that these acids drew alkali from the blood. The body had a very remarkable source upon which to draw for alkali. This was the ammonia produced either by the tissues in the course of normal metabolism of the proteids, or the ammonia produced by the splitting off of certain ammonia-containing substances from the nitrogenous food. Meat, for instance, yielded a considerable quantity of free ammonia. This ammonia was normally converted into urea; from twenty to forty per cent. of all the urea originating this way. When acids were produced in excessive quantity, the ammonia which normally went to the formation of urea was diverted to neutralize the acid and carry it out of the body. This was the reason why in severe diabetes the ammonia was regularly increased in the urine if the acids were formed in excess. The principal acid was beta-oxybutyric acid, which might break down into acetone and diacetic acid. This acid came in part from proteid and in part from fat, and it might be that the feeding of large quantities of fat and meats in the later stages of diabetes was harmful. It should be borne in mind that these acids were undoubtedly the cause of diabetic coma. In this form of coma the respirations were usually deep and rapid, and there was considerable dyspnœa, though there was seldom any cyanosis. The explanation of these facts was to be sought in the peculiar condition of the gases in the blood and in the cells. On the introduction of an acid into a cell a certain amount of alkali was withdrawn—ultimately sodium and potassium. As soon as this had been done there was no opportunity for the formation of carbonates, which were necessary for the transportation of carbonic acid out of the cell. This resulted in a condition of asphyxia in the cell. Under these circumstances there was no diminution in the amount of oxygen in the blood, yet the cells could not get at the oxgyen, the carbon dioxide preventing the exchange of the gases. The quantity of carbon dioxide under these conditions was enormously diminished. There was no reason to believe that these acids acted through any special toxic effect of their own. The kind of acid was not of importance, as the same condition could be brought about by the administration of hydrochloric acid or other mineral acids.

Treatment.—In the precomatose stage of diabetes a very great deal could be done in the way of treatment by recognizing the important part played by these organic acids in the blood. If such persons were given large doses of sodium carbonate steadily and persistently they would be greatly improved and life prolonged.

Diabetes Induced by Phloridzin.—Dr. Graham Lusk said that some years ago, when he began the study of diabetes with Professor Boyd of Munich, the latter had expressed to him the belief that diabetes was the result of the non-combustion of the carbohydrates. To understand this subject the fact should be recalled that the fæces were only in very small part the residue of the food, but rather the residue of the intestinal juices and substances discharged into the intestinal canal. To determine the quantity of proteid decomposed in the body one should estimate the sum of the nitrogen in the urine and fæces in the twenty-four hours. Under normal conditions a reduction in the carbohydrates caused a largely increased proteid waste. Every gram of nitrogen in the urine represented the destruction of 6.25 gm. of the body proteid. The sugar was proportionate to the proteid decomposition. He was inclined to doubt the truth of the experiments cited by the previous speaker as showing that there was a production of sugar from fat, because these experiments had been made in only one laboratory and were totally opposed to the results obtained by many other experimenters. It had been claimed by some that gelatin was a good foodstuff for diabetics, but in an experiment that he had conducted in feeding this substance to an animal, the result showed, as might have been expected, that just as much sugar was produced as when proteid was used. Our object should be to find a sugar which could be burned in the body, as this would result in the reduction of the acids referred to. Both levulose and galactose were burned in the body to a certain extent.

Glycuronic Acid in the Urine, and its Distinction from Sugar.—Dr. John A. Mandel presented this phase of the subject. He said that as long ago as 1879 it had been noted that the urine of a dog which had been given camphor reacted as sugar ordinarily did with the usual tests. Long before this time it had been known that chloral hydrate, trichloral, butyl alcohol, and other substances, when introduced into animals, were eliminated along with some body having a reducing action on Fehling's solution. Under certain conditions dextrose was apparently oxidized in the blood into glycuronic acid. The latter acid could be easily obtained by decomposing the urine of a dog to which chloral had been given. Pure glycuronic acid was a non-crystallizable syrup, and a dextro-rotary body. The compounds found in the urine which were derived from this acid apparently polarized to the left. Although closely related to dextrose it did not ferment. It formed compounds with phenylhydrazin, which were amorphous and had a low melting-point. Glycuronic acid reduced Fehling's solution—indeed, the common tests for dextrose in the urine responded markedly with glycuronic acid, and this constituted the chief source of the pseudo-reactions for sugar. The administration of drugs of the aromatic series, or of the fatty series, *e.g.*, eucalyptol, creosote, guaiacol carbonate, the coal-tar products generally, betol, resorcin, etc., resulted in reactions which might easily be mistaken as an indication of the presence of sugar in the urine. After the administration of chloroform or of morphine such reactions might also occur. To distinguish these false reductions from the true reaction one should resort to the old reliable fermentation test. A glycuronic-acid urine would not yield carbon dioxide on fermentation. Another distinguishing feature was that the phenylhydrazin test yielded an amorphous instead of a crystalline deposit, as demonstrated by microscopical examination. Another test for glycuronic acid and pentoses was to add to the urine an equal quantity of hydrochloric acid, and then a tiny portion of phloroglucin, and heat. The characteristic reaction of such urine was a red color.

Cause of Lipæmia.—Dr. Louis Faugères Bishop referred to a fatal case of diabetic coma in which at autopsy the blood had been found in a condition almost like cream—a lipæmia—and he asked Dr. Herter regarding the relation of this condition of excessive fat in the blood to diabetes.

Dr. Herter replied that a very considerable excess of fat in the blood had been observed a number of times in diabetes, but always in exceptionally severe cases. The explanation seemed to him simple. The organism was practically in a state of starvation; it was living on its proteid and on its fat. In a state

of starvation about twenty per cent. of the caloric of the body came from the burning of the proteid molecule, and the remainder from the fat. Patients in this condition were living largely upon their fats, and the fats accumulated in the blood because in such bad cases the organism was unable to burn either fat or sugar.

Dr. A. Mayer said that two Vienna observers had recently found that within one hour after phloridzin had been administered the quantity of sugar in the blood was greatly increased. They had also observed that the venous blood in these cases contained a great deal more sugar than the arterial blood. From this it would seem that the diabetes produced by phloridzin was entirely different from what the physician understood by that term. It was not improbable that diabetes was after all only a symptom. Again, the sugar did not exist in the blood in a free state, but in the form of a chemical compound. The sugar of phloridzin diabetes was entirely different in appearance from the sugar obtained from the blood in the healthy state. In undoubted cases of diabetes in which perhaps the pancreas or liver was involved it was not uncommon for tuberculosis to be an intercurrent disease, and under these circumstances the sugar would disappear from the urine. It seemed to him if diabetes was a disease of the pancreas it should not be affected by such an intercurrent disease. A recent experiment of some significance was the feeding of diabetic urine to dogs and the production in them of glycosuria. If the diabetic did not burn up his sugar the body temperature would be subnormal, which was certainly not the case, as he had abundantly proved by numerous thermometric observations. The sugar, therefore, he thought must come from the tissues, and not from the food.

Dr. Herter said, regarding the experiments quoted as to the quantity of sugar in the blood after the administration of phloridzin, that these investigators had not published the method by which they had estimated the sugar, and until they did this he did not feel warranted in placing much reliance upon their results. His own observations had been made by a method which he believed to be absolutely reliable, and his results had been in accord with those obtained by Dr. Lusk and others. The scepticism that the last speaker had expressed regarding pancreatic disease was one which he knew was shared by many others, yet he himself believed that recent and most carefully made autopsies would support the statement that the pancreas was almost uniformly diseased in diabetics. The method that had been employed in the experiment of administering diabetic urine to a dog seemed to him so faulty that he could not draw any positive conclusions from it. If the organism could not secure a proper degree of animal heat from carbohydrates it would secure it from the fats, or even from proteids. There was probably no case of diabetes in which there was not at least a small proportion of sugar burned.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, January 21, 1901.

Parker Syms, M.D., President.

A Pathological Condition of Houston's Valves.—Dr. James P. Tuttle exhibited this specimen, and called attention to the nature of these valves, which normally existed in the rectum. The specimen showed a hypertrophied condition of the valves. He said that it was now a little over seventy years since Houston had first described them, and since then, particularly in recent years, there had been much discussion regarding not only their function, but even as to their existence. Drs. Martin and Pennington had recently directed special attention to them, but Matthews, of Kentucky, was still one of those who denied the existence of the valves. The specimen had been taken from a man about forty-five years of age. The rectum was almost occluded by two folds of mucous membrane under which ran fibres of the connective-tissue base. The existence of the valves could, therefore, not be doubted, though they were developed in varying degree in different individuals. It was supposed by some that these valves acted as a support for the fecal column, and as an additional protection to the lower end. Another theory was that they were simply plicæ or folds of mucous membrane, and that their object was to furnish a greater redundancy of mucous membrane to allow of sufficient distention of the gut. Recent observations, however, had shown that these folds stood out boldly as folds or bands when the rectum was greatly distended. The speaker said that he was not disposed to exalt the function of Houston's valves to such an extent as had Drs. Martin and Pennington, but it seemed to him not improbable that in certain cases they might be responsible for that form of obstinate constipation styled obstipation. An instrument was exhibited by means of which these folds could be safely destroyed when it was found that they offered any serious obstruction.

Lupus Treated by the Galvano-Cautery.—Dr. W. S. Gottheil presented a young woman who had been under observation for several years. She was presented to show the effect of an old method of treatment. The site of the former eruption was now covered with smooth skin of almost normal appearance. The treatment employed had been the destruction of the nodules with the galvano-cautery. It had necessarily been carried out irregularly, but had occupied altogether not over two months.

Lupus Vulgaris Treated by Static Electricity and the X-Ray.—Dr. A. C. Geyser read a paper on this subject, and gave a demonstration of the technique. He said that when lupus vulgaris attacked the face, nodules were at first buried under the skin, arranged in groups of irregular size and shape. The intervening skin became reddened and infiltrated. The nodules projected above the surface. They soon underwent degeneration, and there was formed within them an irritating fluid. The prognosis, so far as life was concerned, was good, but a spontaneous cure could hardly be looked for, and if it occurred it would be only after the formation of extensive and disfiguring scars. Caustics, to be effectual, must be severe in their action. The nearest approach to a specific treatment for this cutaneous disease was that with the Roentgen ray. The property of this ray to act either superficially or deeply was specially valuable. The patient was seated behind a screen of lead perforated over the area to be treated, and having a rim around this perforation. A "soft" tube should be used, such a tube as showed the bones of the wrist white, and not having sufficient penetration for the ordinary surgical uses of the *x*-ray. If too much pain resulted from the application the static spray should be temporarily substituted for the *x*-ray. The exposures might be made daily at first, and later on at intervals of a week. The worst case that he had treated, one of nine years' standing, had received forty treatments; others had been cured after eight or ten treatments. Out of eleven cases treated by this method, eight had been completely cured with little or no disfigurement; three were now under treatment with every prospect of an excellent result. Two patients were presented in illustration of what could be accomplished by this method. One of them, a young woman, had been treated previously for a period of several months in

almost every dispensary in this city, and had been treated by him since last March. In the man presented the *x*-ray had been used on one side of the face, and the static spray on the other side. The side treated by the *x*-ray was free from hair and quite smooth.

Dr. Gottheil said that Dr. Geyser was certainly to be congratulated on what he had accomplished. Some of those present had seen the young girl previously, and had declared that the result was most remarkable. Such results were new to him in the treatment of lupus vulgaris. Neither of the cases presented had been entirely cured, and he would like very much to see one that had been fully cured. The light treatment had been largely used in the treatment of these cases, but its great drawback was the many months required to effect a good result. The *x*-ray treatment had the disadvantage of requiring expensive and cumbersome apparatus, but it was certainly suitable for the very bad cases.

Exophthalmic Goitre of Syphilitic Origin.—Dr. R. Abrahams read a paper with this title, and reported three cases of this kind. The first was that of a woman of thirty-five who, in the spring of 1894, had contracted syphilis from her husband. She had come under treatment when there was a profuse eruption. This had disappeared quickly under mercurial inunctions, and the patient had then refused to continue treatment. Six months later she had returned with mucous patches in the mouth, and inspection had shown a bulging of the eyes, which she said had first been noticed two months before. At the same time she had suddenly become very nervous, and had suffered from dyspnœa and cardiac palpitation. The thyroid was large, soft, and pulsating. An attempt had been made to treat the exophthalmic goitre by the usual remedies, such as strophantus, digitalis, ergotin, arsenic, and iron, but with absolutely no benefit. She had then begun to suffer from severe nocturnal headache, and to relieve this she had been given a saturated solution of the iodide of sodium, beginning with a dose of gtt. xv. and running it up rapidly to ʒ ii. The headache had been promptly relieved, and in two months all of the symptoms of exophthalmic goitre had disappeared. The result of this treatment had deeply impressed him. The second case was that of a woman thirty-six years of age, the mother of five healthy children. In 1894, shortly after the birth of her last child, she had had a sore on the vulva, followed by enlargement of the inguinal glands, and later by an eruption, sore throat, and falling of the hair. She had not been treated by any physician at the time. On coming under observation in 1896, she gave a history of three spontaneous miscarriages, and examination showed a perforation of the hard palate and an exophthalmic goitre. She sought treatment chiefly for a swelling in the neck. Under mercurial treatment a cure of the goitre had been effected in a short time. The third case was that of a single woman twenty-seven years of age, who gave a distinct history of syphilitic infection. At first there had been cardiac palpitation, and there had developed slowly an enlargement of the thyroid. She had been treated with a saturated solution of iodide of sodium in large doses. In less than a month the improvement in the goitre had been very decided, and she had been restored to perfect health in ten weeks.

Dr. C. W. Allen said that, as little was known about the etiology of exophthalmic goitre, it was most important to give heed to any means or suggestions along this line that might be offered. Syphilis had often been mentioned as a predisposing cause, but he believed it was new for syphilis to be presented as the predominant etiological factor. For this reason he could not agree with the reader of the paper that antisyphilitic treatment should be given a trial even in cases in which there was no syphilitic history. Iodine and mercury had long been known as useful remedies in Graves' disease. Many cases had been treated successfully in this country by the external application of iodine, usually combined with belladonna. So far as he knew there had never been on post-mortem examination of a case of this disease any indication of the existence of syphilis.

Dr. W. M. Leszynsky said that in a rather extended experience he had not met with a single instance in which he could consider syphilis as the cause of Basedow's disease. In young women there was not infrequently a perceptible enlargement of the thyroid gland associated with some protrusion of the eyes and tachycardia. This disappeared spontaneously. From his experience and from a knowledge of the literature of the subject, it seemed to him probable that syphilis might act as a predisposing factor through the anxiety and mental depression often produced in a patient by a knowledge of having contracted syphilis. It was pretty well agreed to-day that one was not justified in saying that an inflammatory exudate was of syphilitic origin merely because it had improved under the use of iodide or mercury. Cases were on record in which the symptoms of exophthalmic goitre had been present and had disappeared spontaneously in a few months. He would like to ask the reader of the paper if rest or any other method of treatment had been employed in these cases.

Dr. Abrahams, in closing, said that no other treatment had been employed in his three cases, and they had been allowed to go about at will.

Cystoscopy in the Female by an Improved Method, with Demonstration on the Cadaver.—Dr. W. R. Pryor read this paper. He said that he had been studying this subject since 1894. The cystoscope used by him consisted of a main tube for inspection, and alongside of this a tube to carry the lamp. He had obtained this idea from an old apparatus devised by some former interne of the Woman's Hospital for draining the bladder. The tube for illumination extended beyond the tube for inspection, and consequently no rays entered the latter—a point of much importance. For removing foreign bodies he had found a long slender alligator forceps better than the forceps used by Kelly. There were three or four different sizes of tubes. The posture of the patient was most important in examining the female bladder. The intra-abdominal force exerted upon the bladder tended to press it into a triangular form. The bladder should, therefore, be distended either with fluid or with air. The disadvantage of using fluid was obvious if one stopped to consider the refraction which light must undergo in passing from air into a denser medium of this kind. Since February, 1894, he had made use of a table which secured the desired posture. If the knee-chest posture were assumed, the very part of the bladder which one most desired to inspect would be out of sight unless special means were employed to prevent this. Dr. Pryor said that in his method the patient was placed on the table, and the bladder emptied. The patient was placed in the lithotomy position and then the head of the table was dropped down to an angle of about 45°. In this position, when air was admitted the bladder assumed approximately the shape of an equilateral triangle. With his instrument every portion of the bladder could be easily inspected, even the pubic and peritoneal surfaces. In December, 1899, he had made his first demonstration with his completed instrument.

Dr. F. Tilden Brown spoke of the different methods now in use for examining the interior of the bladder, and expressed the opinion that the segregator method was inexact. The method just demonstrated

was of the Pawlik-Kelly type, and appeared to be a great advance on that so long and so successfully practised by Dr. Howard Kelly. The knee-chest posture formerly employed was a very distasteful one to the patient and a very inconvenient one for the examiner, and that position seemed no longer necessary in view of the results obtained with the exaggerated Trendelenburg position employed by Dr. Pryor. The instrument just presented was one which he could only praise. The method seemed to him very suitable for class-room demonstration, and also useful because it allowed of the simultaneous collection of the urine separately from the two ureters. Specimens so obtained could be more accurately compared than if the two specimens were collected a few minutes apart, and when perhaps the mental and nervous state of the patient was not the same. The great disadvantage of the Kelly method was that it was practically applicable only to the female. Another disadvantage was that even the smallest tube was pretty large for the female urethra, and its introduction must cause considerable pain. His own practice was to make use of a double-barrelled instrument, by means of which the urine coming from both ureters could be simultaneously collected.

Dr. Pryor said that he ordinarily made use of an instrument measuring 1 by 1.3 cm. and that general anæsthesia should be used to secure the best results. The use of the double-barrelled instrument seemed to him faulty because if tubercle bacilli were present in both samples of urine it did not by any means prove that both kidneys were the seat of tuberculosis. Such an examination must be faulty if made through fluid. Harris' method was an absolute failure. To be quite exact in such an examination he believed that it must be made through a ureteral orifice which had been cleansed, and the method should be such that the catheter could be introduced directly into the ureters without touching other parts. His method was certainly useful for class-room demonstration, but that was not its chief object; it was only an incident.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

BEER POISONING, THE EXTENDING EPIDEMIC—DISCUSSIONS AT LIVERPOOL INSTITUTE AND LONDON MEDICO-CHIRURGICAL SOCIETY—THE BIRTH RATE—THE LATE DR. JACOB.

London, January 18, 1901.

Some more deaths from poisoned beer; cases in fresh localities; reports of inquests, these are items that still meet us in every newspaper, while our professional journals teem with contributions to the great scare. The most remarkable bit of evidence in some respects is the confession in the coroner's court that a firm supplied impure sulphuric acid to the manufacturer of glucose instead of the pure article as previously supplied.

In view of the increasing mass of materials and evidence, I will to-day deal with the two discussions I have already mentioned; but even of these your space will admit only a cursory notice.

There is this difference between the two principal discussions on arsenicated beer: at the Liverpool Institution speakers and audience were in the midst of the epidemic; in London, though Dr. Reynolds, of Manchester, came up to open the debate with a record of his experience, he was followed by speakers who could treat the matter only from a more or less academical point of view.

To begin with Liverpool—Dr. Nathan Raw opened the discussion, saying he had had one hundred and forty-eight cases under his care during the last twelve months, and most of them seemed alcoholic. But in the later cases the symptoms were more like acute irritant poisoning. He traced the first serious contamination of beer with arsenic to last May, and a sudden further increase to November. He suggested that the effects of arsenic were modified by alcohol.

Dr. Reynolds, of Manchester, related the steps taken to trace the origin of the epidemic, and spoke of the great heart weakness observed in the cases.

Dr. Stansfield, of Birkenhead, said he usually saw three or four cases of peripheral neuritis in the infirmary in the course of a year, but since October they had increased to thirty-two. He, too, thought arsenic more potent in beer.

Dr. Barendt spoke of the rashes after (*a*) heavy and (*b*) moderate drinking, and said some had been mistaken for cutaneous diseases of different origin—the pigmentation being often taken for a sign of Addison's disease.

Dr. Glynn had seen some cases occurring after only a few glasses of the contaminated beer had been imbibed, but could not accept the suggestion that alcoholic neuritis was always due to this, for he had seen cases in spirit drinkers who took no beer.

Dr. Carter said it needed some such outbreak to startle the country. The traffic in alcohol was constantly increasing, and the death rate due to it continually rising. A great fall in the death rate of Salford had been reported since the alarm had led to less beer drinking. He urged the duty of the legislature to prevent the adulteration or contamination of beer.

Dr. Hope related how the brewers had destroyed large quantities of beer as soon as they heard of the poisoning; more than 180,000 gallons being poured into the Liverpool sewers.

Dr. Leslie Roberts described the cutaneous symptoms observed, which he divided into a chronic vasomotor group and a nutritive group.

Dr. Newall remarked on the sudden outbreak in Chester and asked if it were possible for arsenic to cause severe, rapid paralysis and marked sensory phenomena without vomiting, diarrhœa, colic, skin affections, or tremors. If not, then the Chester cases must be due to some other cause.

Dr. Prytherch said there was much evidence that the Chester cases were really beriberi, and in this he was supported by Major Ross. He did not even admit that the finding of arsenic in the urine was conclusive proof.

Dr. J. E. Nevins found the cases in the Liverpool Parish Hospital milder than in the West Derby Hospital, and had noticed much freckling in arsenical cases with or without other pigmentation. Freckles were marked and more frequently present in these cases.

Dr. J. H. Abram said most of his cases had no pigmentation. In the absence of skin lesions examination of the urine should not be delayed. The failure to detect arsenic was sometimes because it had been eliminated.

Dr. D. Smart, though medical officer to a workhouse, had had no cases definitely due to arsenic. He had had seven cases of neuritis which, though examined by others, could not be traced to the poison.

Turn now to the debate at the Medico-Chirurgical Society begun on the 8th and adjourned to next week. It was opened, as I said, by Dr. Reynolds, of Manchester, who detailed the steps by which he was led to the discovery that the epidemic originated in poisoned beer. First he noticed an unusual number of skin diseases, then he observed that these were associated with peripheral neuritis which had also been more prevalent. Remembering that herpes might be produced by arsenic, he suspected the drink which seemed to be the cause of the multiple neuritis. On analysis by Professor Delepine arsenic was found in the beer, then in the invert sugar and other substances used in brewing. Many thousands had suffered in the northern and midland districts. The patients complained of "pins and needles" pains in the feet and limbs, tingling in the soles of the feet, difficulty of walking, general weakness, swelled feet, vomiting, and diarrhœa. Numerous skin symptoms appeared with pains preventing sleep. The puffiness of the face, especially about the eyelids, and the peculiar walk were characteristic. The nervous system was extensively affected, the symptoms closely resembling those of alcoholic neuritis. There was intense tenderness of muscles, but sometimes partial anæsthesia. The heart was gravely affected and death often ensued from this. Catarrh of mucous membranes was commonly observed. Vomiting occurred in seventy-five per cent., and diarrhœa was as frequent. The urine in some cases contained arsenic a fortnight after leaving off the beer. The poison was also secreted in the milk. In some cases the temperature rose. Summing up his observations on about five hundred cases, it appears that the poison affects the skin, the respiratory and digestive mucous membranes, the nervous system, the heart, and the liver. The cases might be arranged in four groups: one in which all the symptoms appear, another in which skin affections predominated, a third in which the heart and other viscera were most prominently involved, and a fourth in which paralytic symptoms predominated. Some patients recovered in a few weeks, others not for eighteen or twenty-four months.

Sir W. Gowers sent a letter pointing out that there seemed some immunity from arsenical poisoning in pa-

tients who took it in combination with bromide and suggesting that alcohol might have an opposite influence.

Dr. Buzzard said the cases seemed largely due to arsenic, though perhaps it might not be the only cause. At any rate he could not admit, as some have suggested, that alcoholic neuritis was only a form of arsenical poisoning. His experience of medication with arsenic or bromides corresponded with that of Sir W. Gowers. A moderate drinker would take only a tithe of the amount of arsenic which an epileptic took in his medicine. No doubt some persons were specially affected by arsenic—he mentioned a case of this in a man taking Fowler's solution, who was severely affected but ultimately recovered.

Statistics show a steady decline in the European birth rate during the latter part of the past century. They also show that the fall in Great Britain has been more marked than elsewhere. England has now the lowest birth rate of any first-class power, except France. The fact is viewed with satisfaction by Malthusians, but with uneasiness by others. Our great trade rival, Germany, has gone ahead of us in this respect. The statistics are not likely to be improved in a time of conflict like this with its terrible losses. It is to be noted that the diminished death rate in some degree discounts the effect of the fall in the birth rate.

Dr. Jacob, of Dublin, died on Saturday, aged sixty-three years, deeply lamented by a host of friends. The name of Jacob as an ophthalmologist and journalist seems inseparable from Dublin. Arthur Jacob, whose name was given to the *membrana Jacobi*, long reigned almost supreme in Dublin among its most distinguished surgeons, and as an oculist and founder and conductor of the *Dublin Medical Press*. At length his son succeeded him in both capacities, and now he has passed over to the majority. He, the son, Archibald Hamilton Jacob, was educated at Trinity, graduated both in arts and medicine, and took the fellowship of the College of Surgeons, of which he was for a long time a councillor and eventually professor of ophthalmology. These positions he held up to his death, as well as the office of ophthalmic surgeon to the Lord-Lieutenant and the House of Industry Hospital. In 1865 our deceased friend purchased the *Medical Circular* and amalgamated it with his own journal. He remained one of the editors to the time of his death, holding naturally entire control of Irish matters, but also writing on other questions. In fact, some of the best articles were due to his ready and forceful pen. In many respects he was a model editor. Rapid in judgment, bold in execution, careless of his personal interests, but entirely devoted to those of his profession, his facile pen was perhaps the most effectual weapon ever wielded for the defence of the medical profession in Ireland. Though he could charge it with terrible sarcastic power, it was only at times he did so when nothing else seemed able to cope with injustice and hoary abuses. His many accomplishments and kindly disposition endeared him to all who had the privilege of his friendship, and outside that circle every medical man in Ireland knew him as the most able champion of his profession.

THE CAUSATION OF RHEUMATISM AND GOUT.

To the Editor of the Medical Record.

Sir: I write this on my back ruminating most sorrowfully as to the subject matter of the above heading. I have been in similar circumstances many a weary time. I have just read Dr. Haig's elaborate paper on gout in the issue of January 6th. It makes me mad. Unlike Dr. Haig, I have never had a gouty headache. When I am laid by the "back," or "heels," whichever may be the correct quotation, my brain is unusually clear. That is why there is room for the madness. Dr. Haig says that rheumatism and gout are one. He thinks they are—I don't. I never had gout, and I don't want it. Dr. Haig is welcome to it. But I have had rheumatism until I am sick of it, and I think I know something about it after nearly a twenty-year experience.

The late Dr. Alonzo Clark, of glorious memory, in one of his lectures said, "Rheumatism is an inflammation of the fibrous tissues." That is one of his sayings which made a plastic change somewhere in my head. That is a story for the nerve men. I bore and saw out noses—when I get a chance. But Dr. Clark was perfectly right. Various fibrous attachments in my composition attest the statement as being good. The uric-acid theory may be all right in some respects, but it don't exactly work in with rheumatic etiological considerations. There is more than one factor at work in producing rheumatism. An inflammation of fibrous tissue may be caused by quite a list of direct and indirect causes. We may have hereditary tendency to hyperæmic conditions of certain tissues, including the fibrous—this being due to acquired habit in ancestors. The inflammation may be due to strain or even unusual moderate use of the misbehaving part. Every attack of miscalled myalgia that I have had, has had such a causative factor included in the etiology. I don't think that muscular inflammation can be taken into account with this disease. Muscular tissue is too elastic in its responses to hyperæmic incursions to be more than sympathetically convulsive when incited by contiguous fibrous tissue. But when those same muscular spasms occur, it sometimes hurts a man like the d—l: as women seem to suffer during parturition. There is usually some irritant or paralyzing element in the blood causing rheumatism. It may sometimes be the poison of gonorrhœa or of scarlet fever; but so far as I can judge, it usually proceeds from a fermentative process in the alimentary tract. I don't think it is uric acid. It is more likely lactic acid. There may be some specific causative bacteria.

Whatever it is, it, in my case, riotously proliferates when I feed it on sugars and starches, rather than proteids. It seems to be more a matter of quantity of food than quality. Whatever influence depresses digestive power acts as an indirect cause, *e.g.*, too much use of the nervous system, or even exhaustive use of the muscular system. If only such food as can be easily digested is put in the stomach there would be little heard of rheumatism. I think that gout is caused by the absorption of more digested nutrients than can be properly oxidized and eliminated. One may call it uric acid, but it originates differently from the irritant of rheumatism and it acts somewhat differently. The two causative irritants may be acting at one time.

Of course the great curative treatment of these troubles is a healthy starvation. The longer I can stand hunger the less rheumatism I have; but in many cases the remedy is worse than the disease. In other cases, however, a perpetual hungry condition is the lesser evil. I have taken this cure partially, but never have been quite able to do so fully. It is not a popular treatment. If any one thinks so, let him apply the principle to some profitable patient, and watch the result on the bank book. In acute attacks, active elimination by brisk catharsis, and restricted diet, along with decided constitutional sedation, shorten an attack two-thirds. In subacute and chronic cases, colchicum, the salicylates, and other sedatives and depressants, are alleviative temporarily, but so far as I can see usually do more harm than good by weakening digestive capacity. The derivative effect of superficial frictions with the horsehair brush, and of deep massage of unaffected tissues, is helpful. So also are hot dry air and hot wet baths, which act eliminatively as well.

But when the local hyperæmic habit is acquired the treatment is slow, unsatisfactory, and frequently unsuccessful; uric acid in one's food to the contrary notwithstanding. Neither in cows nor in men can the depreciative effect of advancing years on an already poorly nourished tissue be escaped—the poorer the nutritive condition of condensed fibrous tissue is, the more is such tissue likely to suffer from unusual strain, and from reflex and direct nervous disturbances. We who have been there know when the east wind blows.

East Orange, N. J.

THE BILL TO REGULATE MEDICAL PRACTICE.

To the Editor of the Medical Record.

Sir: The profession must know, of course, that a bill has been introduced in the legislature of this State, the purpose of which is to enable those who are empowered to do so, to enforce the medical laws. As at present interpreted these laws can be enforced only against illegal practitioners who give medicines. If a person desires to evade these laws, all it is necessary to do is to adopt some peculiar title, as Christian Scientist, osteopath, hydropath faith curist, or even no name, refuse to give medicines or drugs, and although such a person may treat disease, there has been, as yet, no lawyer who will advise action against such an illegal practitioner. The law as at present enforced is an incentive to uneducated people to adopt some of these peculiar names or methods, and they can prey upon the community with impunity and without molestation.

The bill under consideration was objected to in the beginning by manufacturers of proprietary articles, opticians, and others, who claimed that its enactment would prevent a person recommending a friend to take a dose of pepsin, or some other simple remedy, and would interfere with the sale of patented articles and in this way hinder the newspapers from advertising such articles.

The framers of this bill had no such intention in drawing the measure, and agreed on its phraseology being altered. As it reads now the bill says that any person shall be regarded as practising medicine who shall give treat-

ment to any other person, by any method whatsoever, for the cure of disease, excepting in an emergency. There can be no valid objection to this bill on the part of patent-medicine manufacturers, wholesale or retail druggists, truss or instrument makers, or any other person who does not make a business of treating disease. Retail druggists have no right now to treat disease, except in an emergency, and this bill will not alter their position nor curtail their rights in any way. The legitimate business of an optician will not be interfered with in any way. This bill is designed to give an increased protection to the public, which is the only reason for the existence of any medical laws. Christian Scientists, osteopaths, and others will have to comply with the law, after which they can continue their peculiar methods if any one can be found to endorse them, or if they continue to believe in these methods themselves. There is no desire to interfere with free thought or religious liberty. There is no desire to prevent any person practising any method his or her intelligence tells them is the best method. We only insist that every person who treats disease shall demonstrate to the State Board of Medical Examiners his or her ability to tell whether a disease exists, how to differentiate the disease which may exist, and then the matter of treatment must be left to individual judgment.

The battle is on, and it will be won by those who believe in protecting the community, if all who so believe will write to the Hon. Nelson H. Henry, chairman of the Assembly Committee on Public Health, giving their names and addresses, and urging the enactment of the bill.

FRANK VAN FLEET, M.D.,
Chairman, Committee on Legislation, Medical Society of the State of New York.
63 EAST SEVENTY-NINTH STREET.

FOR RELIEF OF STOPPAGE OF TEAR PASSAGE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The device described in the MEDICAL RECORD of this date by Dr. E. A. Pond, of Bangor, Me., "For the relief of stoppage of the tear passage," etc., is one that has been in use by Dr. W. W. Vilas, of El Paso, Texas, for a number of years. It was described by Dr. Gallagher, of El Paso, in a medical paper four years ago. The difference is that Dr. Vilas' method is better. He has a small tube —which I have seen; this he passes down the duct into the nose. Through this he passes a silver wire or silkworm gut suture and then removes the tube, leaving the wire or gut *in situ*. He then clamps a shot onto the lower end of the wire and pulls it up into the nose. A perforated shot is then run onto the wire above and clamped close to the upper outlet of the duct. The wire or gut is then cut close and the patient is discharged.

I once asked the doctor how long he allowed this to remain. "Until the patient returns," he said. As he has practised over a wide extent of territory, this may not be for weeks.

This was but one of many valuable suggestions I learned from the physicians who practised in the Southwest before the era of railroads.

I believe Dr. Vilas was the first man west of the Mississippi to stain and see Koch's bacillus.

F. V. CANTWELL, M.D.
TRENTON, N. J., February 2, 1901.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 2, 1901:

	Cases.	Deaths.
Tuberculosis	282	190
Typhoid fever	27	15
Scarlet fever	336	14
Measles	116	2
Diphtheria and croup	361	40
Smallpox	50	2

Green Hair in Copper Workers.—In the *Deutsche medicinische Wochenschrift* (43, 44) Dr. Lewin, of Berlin, gives an exhaustive survey of the effects of absorption of copper on workers in that metal. His conclusions are that a true chronic copper poisoning does not exist, though the rapid absorption of considerable quantities of the metal by the respiratory or digestive organs may produce a feeling of malaise. The chief chronic effects are seen in the teeth, gums, and hair. The formation of a green or dark blue "patma" is frequent on the former and is found to contain a large proportion of copper. Green hair is less common, Dr. Lewin having found it in only eight out of three hundred copper workers. The color gradually disappears when the work is given up, and the question whether the copper is deposited within the hair or excreted on its surface appears still unsettled.

Arsenicated Beer.—The *London Times* comments as follows on the above subject: "There is no difficulty in seeing how arsenic might make its way into beer. Indeed, the thing is so simple that the difficulty is to understand why, if beer is the source of the mischief, poison symptoms did not force themselves upon the medical attention years ago. Most people are probably dimly aware that modern beer is made from a great many substances besides the malt and hops from which it was exclusively derived in more primitive ages. The alcohol produced by fermentation comes in all cases from the decomposition of sugar, but the origin of the sugar is immaterial so far as the alcohol is concerned, though it exercises an important influence upon flavor. . . . The sugar now largely used in brewing comes either from low grades of cane sugar or from some cheap form of starch, most commonly the starch of Indian corn. In both cases the conversion into brewing-sugar is effected by treatment with sulphuric acid. Now, commercial sulphuric acid is largely made from pyrites, which yield sulphur on roasting. But they also contain arsenic, and arsenic is volatile at the temperature employed. Consequently arsenic passes over with the sulphurous vapors which are led into the acid chambers and finally appears sometimes in very considerable quantity as an impurity in the resulting sulphuric acid. We have only to suppose that the maker of brewing-sugar uses this arsenical sulphuric acid to convert his maize starch in order to understand how arsenic in appreciable quantity may find its way into beer. Arsenic may be said to be invariably present in commercial sulphuric acid, but it is naturally present in far larger quantities in some samples than in others. . . . It remains to be seen what breweries have been supplying arsenicated beer. There is no excuse for them if they have been using arsenicated sugar without knowing it. They ought to ascertain for themselves the purity of the ingredients they use, and if they have no chemist on the premises capable of conducting the exceedingly simple and conclusive tests for arsenic, their negligence is culpable."

Influence of Fatigue in the Causation of Typhoid Fever.—Bodily fatigue and mental worry apparently increase susceptibility to typhoid fever. The effect of fatigue is especially observable in armies. However, there are certain points connected with the study of this subject that are not altogether clear, and there is a possibility of falling into error in formulating conclusions concerning the relation between fatigue and typhoid fever. In the first place, exhaustive physical exertion, as is instanced after prolonged forced marches with raw troops, may cause a continued fever which resembles typhoid fever clinically, but is wholly different in its etiology and pathology. This fever of exhaustion may continue for two or three weeks and may be mistaken for typhoid fever. However, it never occurs in epidemic form. It has been observed that within two or three days after a forced march or other

exhaustive exercise the number of typhoid-fever cases increases. The short time elapsing between the exercise and the appearance of the fever does not justify the belief that infection occurred during or after the exercise, but in many of these cases infection must have occurred before the physical exercise, and the only effect attributable to this is that of causing the more speedy development of the disease in persons already infected. It is true that physical exhaustion may, and probably does, increase susceptibility to typhoid fever; this probably is brought about by lowering the resistance of the body against an infection. —Report on the origin and spread of typhoid fever in United States military camps during the Spanish war of 1898.

Use of Obstetric Forceps.—For a delay in the second stage of labor, arising from (*a*) uterine inertia, (*b*) small-size vagina, (*c*) rigidity of maternal tissues, (*d*) obstruction from bands, (*e*) large size of head, (*f*) want of flexion, (*g*) pelvic deformity. For delay in first stage, (rarely) as in (*a*) placenta prævia, (*b*) rigidity of the os uteri, (*c*) absence of a natural dilating agent. For certain accidents in labor in any stage, and when rapid delivery is indicated, as, (*a*) convulsions, (*b*) prolapse of funis, (*c*) excessive uterine action, menacing rupture. For certain secondary purposes, as for (*a*) extraction of the child after rupture of the uterus, (*b*) for removing tumors and foreign bodies from the maternal passages.—Dr. W. J. Gillette, *The American Medical Compend*, November.

The Hydrostatic Test of Still-Birth.—Dr. Dilworth records a case which shows how careful one must be in accepting the trustworthiness of the hydrostatic test of still-birth, at any rate when some days have elapsed before the examination of the body has been made. Owing to some rumors an inquest was held on the body of an illegitimate female child, which was exhumed after being buried ten days. The evidence given at the inquest went to show that the child had been born rather precipitately, but that the woman had been attended first by some neighboring woman, then by a medical man, and finally by the parish nurse, all of whom saw the baby alive though weakly. At the post-mortem the body was found to present the appearance of a child born at full term and fairly well developed. When the chest was opened the lungs were found collapsed, not filling the chest cavity, and in a state of complete atelectasis. On resort being had to the hydrostatic test it was found that the lungs sank when both were immersed together, when immersed separately, and even when small portions were thrown in—in fact, they presented all the appearances found in the lungs of a still-born child. The matter seems of some interest as emphasizing the doubt which has been often expressed as to the reliability of this sign of still-birth.—*The Hospital.*

The Increased Prevalence of Appendicitis in Switzerland.—*The Lancet's* Zurich correspondent writes that Dr. Haemig, first assistant of Professor Krönlein, made an interesting communication on December 6th at a meeting of the Zurich Medical Society, on a series of cases of appendicitis observed at the surgical clinic of Zurich from 1881 to 1900, the number of years during which Professor Krönlein had been in charge of the clinic. The number of cases admitted increased from year to year, so that against 45 cases in the first fifteen years there were respectively 13, 21, 35, 41 and 48 cases of admission in the last five years. Of these 203 cases, in 35 there was no operation, 5 of the patients being in a hopeless condition, and in the other cases operation being considered unnecessary. Fifty-one patients had to be operated upon in the acute stage for abscess, 4 of these cases terminating fatally; in 27 cases generalized peritonitis had already supervened, and of these 21 terminated in death, notwithstanding immediate operation. Ninety-one patients were operated upon in the "free interval," and all recovered. The mortality percentage of the cases was 14, but if only the cases operated upon in the "free interval" be considered it will be seen that 142 cases had a mortality of only 3½ per cent. Dr. Haemig laid due stress on the desirability of operating in the "free interval" and if possible after the first severe attack of appendicitis. The fact of the greater prevalence of appendicitis among men (70 to 30) is accounted for, he considers, by the better blood supply of the appendix in females.

The Germicidal Properties of Ethylic Alcohol.—Bertarelli (*Il Policlinico*, October 1, 1900) has tested the germicidal properties of ethylic alcohol in various strengths from twenty-five per cent. to one hundred. Silk threads were impregnated with various bacilli (for example, B. prodigiosus, pyocyaneus, staphylococci, vibrio, B. typhosus, etc.), then immersed in alcoholic solutions of various strengths. From these researches alcohol appears to have only a moderate antiseptic value, and the more concentrated the solution the less the antiseptic power; fifty-per-cent. solutions are the most efficacious. Perhaps the comparative inefficiency of the stronger solutions is due to the fact that they cause greater coarctation of the peripheral masses of bacilli and so leave the central masses more or less untouched. In spite of its low bactericidal properties alcohol hinders the development and later vital manifestations of the micro-organisms. Alcohol appears to have an inhibitory effect on the antiseptic power of certain germicides (for example, corrosive sublimate) dissolved in it, and the greater the alcoholic strength the greater the inhibitory power.—*British Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended February 2, 1901:

		Cases.	Deaths.
Smallpox—United States.			
District of Columbia, Washington	January 19th to 26th	2	
Florida, Jacksonville	January 12th to 26th	10	
Illinois, Chicago	January 19th to 26th	25	1
Indiana, Michigan City	January 20th to 27th	1	
Kansas, Wichita	January 19th to 26th	9	
Kentucky, Lexington	January 19th to 26th	2	
Louisiana, Shreveport	January 19th to 26th	5	
New Orleans	January 19th to 26th	11	3
Maryland, Baltimore	January 19th to 26th	1	
Pennsylvania, Erie	January 19th to 26th	1	
Pittsburg	January 19th to 26th	2	
Tennessee, Memphis	January 19th to 26th	8	
Nashville	January 19th to 26th	4	
Texas, Houston	January 19th to 26th	44	1
Utah, Salt Lake City	January 19th to 26th	31	
Wisconsin, Milwaukee	January 19th to 26th	1	
Smallpox—Foreign.			
Belgium, Antwerp	December 29th to January 5th	1	
Brazil, Pernambuco	November 15th to 30th	..	30
China, Hong Kong	December 8th to 15th	1	
Egypt, Alexandria	December 24th to 31st	2	1
England, London	January 5th to 12th	1	
New Castle, on Tyne	January 5th to 12th	2	
France, Paris	January 5th to 12th	..	11
India, Bombay	December 24th to January 1st	..	4
Mexico, Mexico	January 13th to 20th	1

THE PROBLEM OF APPENDICITIS FROM THE MEDICAL AND SURGICAL POINTS OF VIEW.[1]

BY ROBERT ABBE, M.D.,

NEW YORK.

MR. PRESIDENT AND GENTLEMEN: When I was asked to address this meeting upon a subject of common interest to us all, I felt that thought and experience justified the choice of a topic of such widespread interest as the one I have chosen, even though the literature of the past few years teems with contributions to the subject. It needs no apology that I should speak of that which has appalled the modern surgical world by its gravity and ravages, and taken from us some of our best leaders and workers—Agnew, Little, Griswold, Lincoln, and a host of others—which has come to the doors of our homes, and strikes so quickly and so fatally when it does come. The subject has few rivals in the surgical field, and takes rank to-day with typhoid, pneumonia, and rheumatism, in medical thought. Surely, when the active surgeon of to-day can number one hundred operations for diseased appendices yearly—and there are a dozen such men in this city and in other cities in the same proportion—we begin to grasp the importance of the subject and its menace to the community.

Surgical propositions and novelties loom up from time to time before the profession with apparent significance, only to be lost to view and to memory in another year. They die young, because the estimate of their importance is erroneous, but this subject lingers in the eye of the profession.

The problems of surgery to-day are fewer than they were twenty-five years ago, although there is vastly more surgical work done. This period has seen great changes in the class of cases that fall into the hands of the operator. Then, strangulated hernias were extremely common; to-day, owing to the vast number of radical cures, they are comparatively rare. Pyæmic joints and abscesses were then the daily care of the surgeon; to-day they constitute a small proportion of active work. Abscess of the kidney, so fatal then, is now relatively infrequent, owing to care in preventing cystitis with ascending infection, due to the use of impure catheters. Aneurisms and tertiary bone lesions are comparatively rare, owing to better understanding of primary and secondary diseases. Tuberculous lesions seem to me, also, to be much less common, owing to more careful isolation of the infected subjects, better house sanitation, and milk and food control. In fact, it would seem that the statement were almost true, that no profession is doing as much as ours to end its own existence. Yet, as soon as one problem is put upon the list as better understood, another comes up for solution. We may rightly take the view that this subject of appendicitis is as capable of expression and demonstration as a problem in algebra. There is yet a widespread division in practice as to the wisest care of any case, but if the theory and knowledge of the subject were presented before two equally discerning minds, they would both arrive at the same logical conclusion. I speak, therefore, of this problem of appendicitis, not with the intention of reviewing its history, or wearying you with statistics, or to exploit any of my own; not to make an exhaustive consideration of the subject, to enumerate the numberless contributions to its literature, nor to reiterate the oft-repeated methods of operation; not even to dogmatize as to what should or should not be done. I would simply present those comprehensive and essential features seen by those of us who come in close contact with the internal appearance of the appendix and surroundings, features which are unknown to the practitioner who rarely sees the diseased organ. Each physician must satisfy his own conscience as to his advice to the patient when he has once comprehended the subject. The question, as still in the public mind, is, "Have we entered on a cycle of epidemic appendicitis analogous to one of diphtheria or plague, or is the conspicuous appearance of the disease like the similar sudden discovery of pneumonia within the professional recollection of most of us?" If it is an epidemic, it will be found to present a group of symptoms unlike those of any disease of previous years, but if it is the result of better understanding of an older disease, classified under a newer name, just as pneumonia was sifted out of the greater group of "congestion of the lungs," which formerly included pleurisy, suffocating bronchitis, etc., then we shall find the symptoms in older text-books so described that we can identify the disease there.

The public continues to ask the physician what was appendicitis formerly, and he answers: Probably it passed under the description of "inflammation of the bowels," or "peritonitis." It is true that less than a generation ago numberless people, in the course of summer travel, were stricken with so-called inflammation of the bowel or peritonitis, and died.

Now, we hear of no one so reported, but it is said, "he had an attack of appendicitis, was beyond the reach of a surgeon and died," or "So-and-so had an attack of appendicitis, was operated upon and recovered." Hospital statistics show the same changes of tabulated diseases. It is merely a new name, not a new disease.

Before we can consider the subject intelligently, we must perfectly understand the morbid condition existing in the appendix, which is the cause of the outbreak. There is no aid to an understanding of the subject at all to compare to seeing the exact physical state of the organ as shown in a large series of preparations. I cannot but feel that if we keep this in the mind's eye, it illustrates every new case which one is brought to face. While it is true there are no two morbid specimens entirely alike, the universality of the presence of internal stricture, of septic infiltration, and of obstruction leads to all the destructive sequelæ.

I wish first to present for careful study a sufficient number of specimens selected from several hundred and arranged in groups of ten which will amply illustrate these facts. Most of these preparations have been

[1] Anniversary address before the New York Academy of Medicine, December 6, 1900.

removed in the interval between attacks, or at the onset of an acute one, and therefore represent the morbid condition always lurking in the part. It has been customary, on removing an appendix, for the operator either to pass into it a probe, or to cut it with scissors, or to drop it into alcohol, for pathological study, where it shrinks to a hard meaningless remnant. But in no such way is it possible to grasp the conditions presented by the disease. The preparations here shown have all been treated by first distending them with alcohol and hardening them in it; then cutting them lengthwise, thereby demonstrating the tightness and number of strictures, the pocketing of the appendix, and the condition of the contained stone in view. (See MEDICAL RECORD, July 10, 1897.) The resulting demonstration is of the utmost interest. One can see most graphically the cause of all symptoms. Observe in this first series, for example, "single strictures." You will see them near the colon in one—near the distant end in another. All are quite tight, permitting only a bristle to pass, and you will see a horse hair passed through some of them to direct the eye to it. In one only of the single strictures, which have been removed for the attacks they have caused, is the size reduced to but a third of the normal calibre, and that gave serious trouble, because the distention of a six months' pregnancy bent the appendix and closed the stricture, producing for the time mild septic symptoms.

Observe others with multiple strictures, each tight enough to permit alcohol to pass through and distend the next cavity in the appendix, so that five or six successive strictures and channels are seen. When removed from the body, these pockets contain mucopurulent fluid, sometimes pure yellow pus, full of infectious bacteria. The colon bacillus is always present, and by authorities is considered the most virulent. The symptoms dependent upon this pathological finding are more apt to be found in the recurrent variety, alternating between a severe colic with slight fever and an attack of so-called indigestion, with three or four days' detention at home. Indeed, it is this, more than other forms, that is found in patients reduced to chronic dyspepsia and invalidism.

Observe another series in which concretions have formed. Many have been found in the cases of interval operation, but more are removed in the acute, grave, septic cases, in which fortune has brought the patient to operation in the first two days before destructive processes culminate.

The ever-present bacterial activity reduces the morbid effete material within the appendix to a condition capable of expulsion into the colon, or of absorption. So bacterial action, ever going on around the rootlets and sacs of the great trees and plants, breaks up and prepares nutrition for absorption from nature's mould and refuse in the earth.

But, as you see in several specimens, a momentary blockade occurs, interior tension rapidly arises, the bacteria are aroused to more virulent action; the walls suffer anæmia, devitalization, and necrosis, and give way at the weakest point, opposite to the pressure point of the stone. Now begins an instant change which has not been hitherto spoken of, but which is demonstrated by scores of specimens, and to understand which, gives a clew to most of the spontaneous cures. Immediately the evacuation takes place, if it be sudden, either by rupture or by overcoming the resistance of the stricture and emptying into the colon, there is a prompt swelling of the lining membrane, which fills the tube and obliterates the space previously filled by the pent-up fluid.

Being impregnated with bacteria, it is inflamed and usually sheds its epithelium, so that a synechia or sealing of the opposing walls promptly follows. If by good fortune the thrown-out material is kindly disposed of by nature, there is an end of the trouble forever. A partial sealing, however, sometimes occurs and a remnant of the canal remains to produce further trouble.

A series is here shown of such overgrowth of the lining membrane and subsequent occlusion, both in the acute septic swollen condition and in the later obliteration, and tells the story to you of many spontaneous cures better than words can describe. The student will not be deceived, however, by thinking that this ending is to any large extent the rule. As a matter of fact, it is the great exception. It tells us lucidly what we all wish to know, how a large number of grave attacks culminate in their own destruction. One or two of the series are of interest in illustrating the fact that even a completely obliterated cavity may leave an atrophied organ, which is the seat of disabling neuralgia, requiring its removal, which ends in restoration to health.

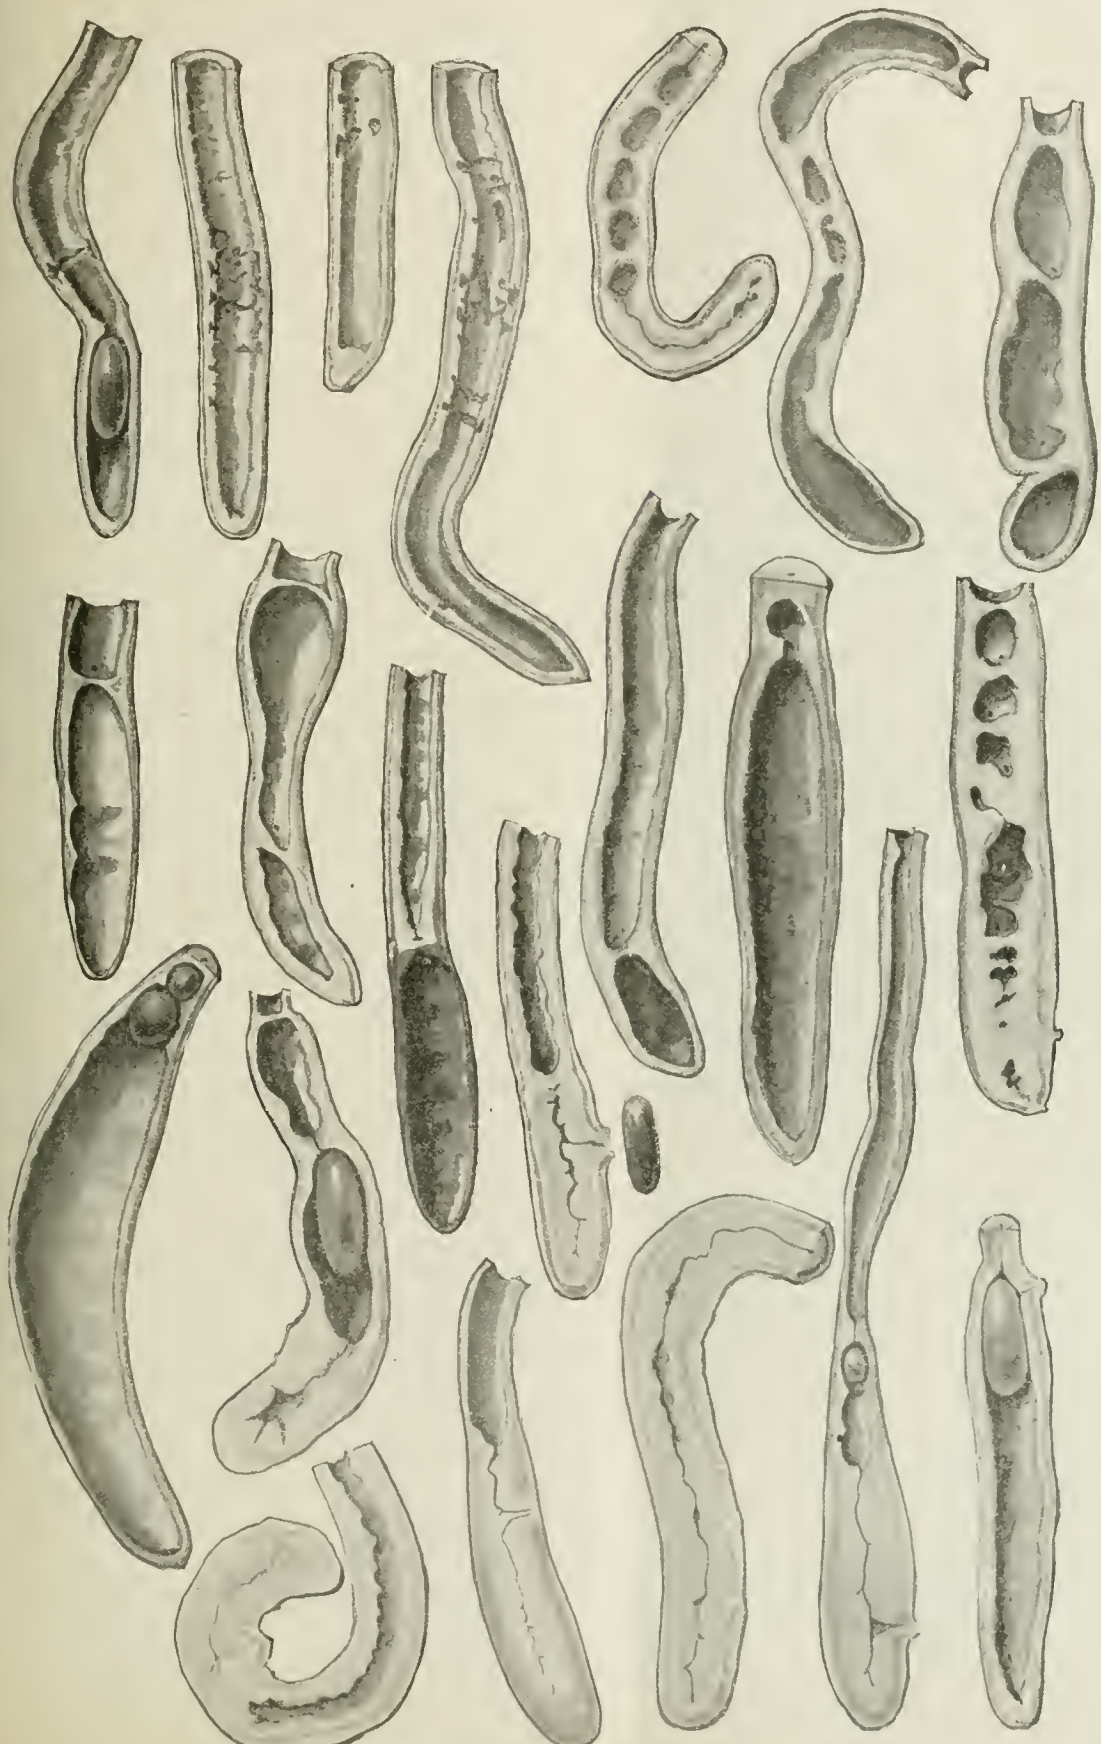
I have arranged one series of appendices, whose interior showed only small follicular septic ulcers. In looking at these, as at the others which have perhaps a more angry appearance, one must supply in imagination the putrefied contents which have been cleaned away in the preparations.

To all students of pathology, however, the ulcerations here shown, with points of entrance for poison, are ample evidence of the cause of slight septic fever accompanying the attack, for which they were removed. In some, the ulcer is a ring-like furrow, half-way or two-thirds around the tube, and, if they progressed to healing, would have in time resulted in linear strictures. It is capable of demonstration that an appendix once thus diseased does not again restore itself to normal health, because of its internal deformity. The detention of its contents, when once a stricture begins to form, converts it, as it has been aptly said, into a veritable culture tube.

The idea embodied in the word "catarrhal" appendicitis is, in the main, a correct one, and yet it so feebly expresses the morbid condition present in an attack of the disease that it should more properly be confined to the initial stage. Excluding the rarer cases in which foreign bodies are entrapped, or in which the kinking of the appendix from its short mesentery produces "obstruction"—the origin of the stricture is found in one of two causes: either the cicatrizing of the septic linear ulcer, or the contraction of the catarrhal inflammation antedating the stricture by many years. The age of the stricture is of the greatest importance in studying the subject. We know from similar contractions, resulting from inflammatory conditions in other parts, œsophagus or urethra, that many years often elapse before the closure is sufficient to give trouble; so in many cases of appendicitis in which study of the removed appendix shows one or more strictures, we follow back the history of attacks from five to twenty-five years, and thus can definitely say that such length of time was taken to develop the final grave conditions. We may say, therefore, that in the earlier years of life an infantile colitis, or a simple influenza, must have been the primary cause of an invasion which lurked in this, the only pocket of the alimentary canal, while the disease was swept from the main channel.

From this study we may say with absolute certainty that the first attack of appendicitis recognized by the patient is in most cases the end of the disease, for the appendix shows the presence of a stricture which must have existed for many years. If one disputes this point and says that strictures sometimes form very quickly, we still have a considerable number of these specimens which we have studied that have behind the stricture a concretion which there is every reason to believe had taken years to form.

At this point let us understand exactly what these concretions are which you see in many of the specimens. Observe, first of all, that they are always on the side of the stricture farthest away from the colon. Their composition is of particular interest. They vary in hardness according to their age. It is rare to find any food products in their composition. They always contain a large proportion of desquamated epithelium mixed with pus corpuscles, the whole teeming with bacteria. If they are of harder variety, they are apt to be laminated and contain needle-like crystals and sometimes calcareous incrustations.



AVERAGE CONDITION OF THE INTERIOR OF THE DISEASED APPENDIX.

Examples selected from several hundred—prepared by distending with alcohol after removal, usually "in the interval" between attacks. Septic follicular ulcers. Strictures, single or multiple, with pockets. Gangrene beyond stricture. Concretions, always formed behind stricture. Spontaneous repair after perforation. Areolar hyperplasia following evacuation. Partial or complete obliteration.

These are indubitable proofs of the long existence of the stricture.

With some recent writers the erroneous idea still prevails that these concretions are formed in the colon and drop into the appendix, dilating it and producing trouble, but the fact that the concretion is always on the distant side of the stricture shows that it has grown where it is found.

Evidence is, therefore, complete that the stone does not begin to form until the stricture has contracted to so small a calibre that the exfoliated epithelium is unable to work its way into the colon in the ordinary process of elimination. Then the fluid contents of this terminal pocket alone pass through and the débris of epithelium left behind, irritating by its presence, begets proliferation, pus cells, and other evidences of decomposition. It is hard to conceive that this process could take less than a few years. I have recently had one case in which a gangrenous appendix containing a concretion had been preceded twenty-five years by a mild but typical attack.

In no case have I found concretions which were not detained by very tight strictures and composed of a desiccated cast-off epithelium of the appendix. These concretions will always be found packed in close to the stricture, which is a most important consideration in understanding the mechanism of acute attacks. The hard oval body acts exactly like ball valve, or like a gall stone in the gall bladder, and when its presence has induced necrotic changes we will almost always find perforation at the point at which it presses.

To return to the possible primary cause of the catarrhal condition, I have twice removed an appendix a fortnight or more after the subsidence of appendicitis in conjunction with an acute attack of influenza, in both of which smart vomiting, fever, and exquisite tenderness of the appendix had ushered in the attack, and in which at operation acute inflammation with follicular ulcers of the mucous membrane of the appendix existed without stricture, thus illustrating that long after the system had thrown off the acute symptoms the appendix harbored this lurking infection. It is fair to presume that several years might have elapsed before the appendix would have had secondary strictures and a new variety of septic disturbance.

These illustrated Draper's suggestion, that in the recent widespreading epidemic of influenza there might be found an explanation of the origin of many a sequel in appendicitis.

It is seriously suggested that gout may be a causative factor in producing appendicitis, in view of the fact that minor attacks are relieved by salicylate of sodium and dietetic treatment, that it is occasionally seen in otherwise gouty subjects, and that mild joint inflammation is sometimes associated. Against this we have the argument that appendicitis occurs largely in youth and childhood; that operation always discloses a mechanical cause for an attack; that the peritonitis is uniformly of bacterial origin and not from gouty irritation; and that the type of joint disturbance is that of a low-grade pyæmic infection.

Above all things, we must consider the mechanical condition revealed in this study as absolutely the essential fact in every recurring attack. The tightening stricture, the multiple pockets harboring the bacterial colonies, and the calculi therein formed, must be remembered by every practitioner as being invariably present in each case of recurring appendicitis. The study of the appendix removed in the interval, when to all appearance the patient has been cured, shows the almost inevitable future recurrence of these attacks. To understand these morbid states elucidates and explains all the symptoms connected with disease, and is the keynote of the entire situation. It stands proved beyond question that, between attacks, the strictured condition frequently shows no tenderness, and usually the appendix is impossible of palpation, even after years of recurrent trouble. I have preferred to speak of this condition as "latent" rather than chronic appendicitis, because the word "chronic" carries with it the idea of ever-present disease, which one would think could be felt, while as a matter of fact this particular organ has the property of hiding itself from discovery between attacks. It presents a "latent" danger, and the term expresses the hidden rather than the chronic aspect of the disease.

Given an appendix with one or more reasonably tight strictures, it is only necessary to produce transient congestion to swell the tissues and block the stricture. Hence it is easy to understand the frequent recurrence of slight attacks, which are seemingly dependent upon such incidents as a violent fall, wrestling, long bicycle rides, eating clams or green apples, or various other accidents, which, to the public, seem adequate cause. The acute attack, however, is really due to the general vascular disturbance of the alimentary canal, in which hyperæmia and excitement the appendix takes part. Even the menstrual disturbance provokes such acute attacks when the trouble is latent. The immediate sequel of the engorgement and blockade is an increased secretion within the shut-off tube. With increased bacterial activity, the size of the appendix is at once inordinately increased by the distention. This is demonstrated by operation done at the onset of the attack, when the surgeon often finds an appendix, which should be the size of a lead pencil and three inches in length, distended to the size of the finger and five or six inches in length. When it is cut away it immediately shrinks to nearly its normal size, but when again distended with alcohol it reproduces the condition found at operation.

In this interesting elongation, the tip of the appendix will be found capable of a wide sweep among the bowels. It pushes across the median line, or to the bottom of Douglas' cul-de-sac, or sometimes upward to the liver. Under this high tension the penetration of bacteria, whose increased virulence is greatly enhanced by the pressure into and through the coats of the appendix, excites an immediate leucocyte exudation, so that thickening and œdema rapidly follow, and the bacteria penetrate the unbroken peritoneum. Without operation one can only conjecture what the early hours of an attack of appendicitis exactly represent, but if a physician could be present and witness the findings on first opening the abdomen during an acute attack, the appalling picture often presented would startle the most conservative mind. Even in most attacks which would subside under medical care the swollen, purple, slimy appendix, often bathed in turbid serum, presents an angry and menacing appearance. This unpromising condition will be quickly overcome when the pressure within the appendix is sufficient to overcome the stricture and discharge its pent-up fluids into the colon. At a later attack, the stricture being tighter, the infection and destruction having proceeded still further, we may see an appendix altered from a mahogany color of capillary stagnation to the poisonous green appearance of beginning gangrene. Nothing more perilous to human life can present itself to the eye of the operator, and yet, gross and threatening as it appears, we see a stage of the decay of the tissues that precedes the formation of abscess in many of those cases which may be even conducted to a natural cure without operation.

Again we find in very early operations the distended appendix covered with thick gray membrane, no less virulent looking than diphtheritic patches in the throat. This seems to be the most severe challenge to nature for cure. The surgeon is prone to present

such gross and offensive organs to the physician for whom he is operating, and challenge the belief that a few more hours would have produced a fatal issue. It becomes the privilege of those who study both the conditions at such a crisis in the disease, and of other conditions discovered at the time of operation in the interval between attacks, to show that nature is perfectly competent to cope with any of the gravest forms of disorganization in a limited number of cases—a very limited number, as attested by the long death roll.

When we have learned from experience that there need be hardly any deaths when operations are properly done, no matter how acute the stage, we see a contrast that does infinite credit to modern surgery.

The glaring inaccuracy of comparative estimates of cures by medical and surgical measures is self-evident when we realize that every case coming to operative cure represents from five to twenty medical cures, for careful search of the histories shows every patient to have been under physicians, time and again, in previous years for a two days' or a week's illness, and each time "cured." I remember, some years since, the illustrious Dr. Loomis told me he sent almost all his appendicitis cases out of the hospital "cured"; that is, he said, "frequently with a small hard lump still remaining inside." So when Ewald says ninety per cent. are cured by medical means, it means only that a lull has occurred, and that "latent" trouble remains each time, though the patient does not feel it then. It is the rarest incident to have a patient unable to recall past attacks, and we must add to those recalled a few more that most patients forget, in the beneficent oblivion to which nature consigns our memory of pains.

We must reconcile the ever-recurring difference between the medical and surgical view of the subject. The physician always wants to postpone, and the surgeon does not dare to take the responsibility of postponing. Why is this? The physician who says he has always "cured" with medicine has made his observations most carefully. That he is conscientious and consistent no one questions, and it becomes the duty of the surgeon to acknowledge to him that the evidence presented in the abdomen, in the region of the appendix, as found by the surgeon in the operation done in the interval between attacks, proves the correctness of the medical view: that, without the aid of the surgeon, nature is often capable of coping with the very gravest complications unaided, and of restoring the parts to almost a normal condition, so that it ill becomes the surgical observer to deny any case of possible restoration to health. It remains with him simply to show that the vast number of so-called "cure" cases are of a mild attack, while the disastrous ones may possibly undergo spontaneous cure, though it be rarely. Some of the exhibited appendices were removed after recovery to health from patients who had unquestionably experienced general septic peritonitis from a rupture of the distended organ, which had scattered its putrid contents widely through the abdomen, begetting a profuse septic effusion, with intestinal paralysis, tympanitic distention, and profound septicæmia. Operation after recovery showed universal intestinal adhesions; a cicatrized point of rupture on the appendix, and concretions and stricture within it, awaiting another opportunity for trouble.

Again, when the preparations are studied by the method demonstrated to-night, one frequently finds, long after grave attacks, the cicatrized perforations sometimes at two points, indicating different attacks, and nothing but a few adhesions to show the remarkable power of nature in clearing up the infection. Around such a point one will occasionally find buried in the adhesions the remnant of an old abscess of large size, dried down to perhaps a teaspoonful of sterile yellow débris. Although this is often seen in other parts of the body, it is nowhere more impressive than when found so close to vital parts.

One noteworthy specimen shows the appendix open at two points into the intestines, where it had discharged numerous calculi, some of which yet remained in it.

It must have happened to every operator, as it has to the writer, either to have been refused the privilege of operation, or himself refusing to operate in cases nearly moribund, that the patients have recovered, more often perhaps by the spontaneous evacuation by ulceration into a neighboring intestine. Yet to the surgeon these cases are no offset to the hundreds of cases of fatal attacks which happen every year, all of which were failures of nature, because of the overpowering infection, and almost every one of which could have been saved by a very early operative procedure. The feeling is growing among experienced operators that no acute case can be at any time more safely operated upon than when first recognized.

Apropos of the query, Why and how do so many of our cases of appendicitis make a spontaneous recovery? we face the marvellous revelations of the intrinsic natural power of recuperation in every form of malady to which our bodies are subject—fevers and injuries as well. We study and we wonder; we speculate on how little human agency has to do with it beyond guiding nature. We aid the fallen giant to his feet, but how little do we do to make him walk. We face the destruction impending in the bacterial warfare against the human organism, and by intelligent guidance we aid the unknown power which restores health. But what that agency is, we do not know. The recuperative power! What is it? Shall we, in this advanced stage of science, still sum it up in the words vital force, that unfathomed thing called "life"? The intelligent act in recovery! Whose was it? Yours, or that something in the patient that made for health? This is an ancient query—not yet answered by the hosts of eager scientists, whose only explanation of the ordinary laws of repair is to acribe to the cells of the body a natural tendency to restore themselves to normal states, a hereditary tendency to right themselves when wrong, and an adaptivity to defend themselves against assault. The human body, as a whole, is considered an intelligent entity composed of orderly but unintelligent cells.

That has always seemed to me an assumption, and, from analogy and observation, I am quite willing to accept the view that every cell is sentient and acts with a purpose by volition, for will cannot be placed in any cell or group of cells, and why may it not be universal? Does not every fibre of the body cry out with pain; does not each organ resent abuse? Lubbock shows the minute insects, like the ant, to be endowed with a high order of reason; they build, colonize, police, go to war, lay by stores for seasonable use, etc.

The individual cells of the swift-growing mushroom can be studied in their life history, confined for a few hours under the microscope, and each cell is said to display affinities and even affection in relation to others.

Why should we, as trained beings, self-classified as of a higher order, arrogate to ourselves the only capacity to deal intelligently with repair in surgical emergencies? Who among us could do anything, did not the extraordinary novel action of each cell lend its aid in new circumstances of its life?

Those which had for half a lifetime repeated their daily growth, death, and reproduction, suddenly spring into activity in a new rôle without our volition. The

healing of even a mere scratch is a study of orderly, exemplary, and intelligent reproduction of cells after a new plan, as if they had been drilled all their lives to wheel into line, and do exactly what was needed, but which was not their previous habit. A hernia suddenly becomes strangulated! At once an intestinal peristaltic action that had for forty years been downward is reversed, as shown by nausea and other symptoms, as if an engineer reversed his engine to avert danger, and why? For no other reason than to help try to pull the loop of intestine out of the pocket in which it was caught.

We think of elaborate warfare of drilled troops, marshalled by thinking generals, as evidence of God-like intelligence. But what of the revelation of science that most diseases are an invasion by bacterial armies which would conquer, were it not for successful resistance of hosts of infinitely small but friendly cells, acting without our control, attacking the invaders, as the picture has been truthfully drawn, and in vast numbers going to their death, as seen in so-called pus, dead leucocytes merely—soldiers on the field after the battle.

But we stand aghast at the methodical procedure of those who met the invading bacteria, embraced and devoured them literally, and thus compassed the recovery of the patient, for which we and the patient take credit. Observe the invasion of tubercle bacillus in a healthy body. Follow the instant array of resisting cells, the leucocyte attack on the foreign invader, the quick hyperplasia of cells, to barricade and surround the group, the starvation of the prisoner, his death, and ultimate disappearance.

Whose is the glory when incipient consumption is conquered? We arrogate too much when man's intelligent action is placed above that of the individual cell.

In laboratory research and philosophical discussion of the still incomprehensible process of repair, as shown in inflammation, it is easy to say "we must dismiss from our minds all ideas which introduce the conception of something in the nature of an intelligent foresight on the part of the participating cells," but only materialistic prejudice will thus beg the question in favor of the not yet proved adaptability of cells to follow only their hereditary and physiological habit of reparative growth. We may say there are certain innate bactericidal and phagocytic properties of cells "called into action" by the presence of inimical poisonous bacteria. Why not, with equal or greater probability, say, "they enter into action"? It is as just to say that a trout jumps at a worm without volition, or that a beaver builds his dam without thought. In realms of beings of higher development than man, he may be regarded as endowed with less will than he now regards the wonder-working amœba.

The imperfect outcome of Nature's repair at times when she signally fails to overcome disease is no more argument for the physiological rather than sentient action of her component cells, than the trout's leap for a false fly, or the beaver's dam being inadequate for a heavy flood, is proof of lack of intelligence.

The more elaborate proceedings of repair, in the terrible emergencies of appendix disturbance in the very centre and vital parts of the body, are seemingly after a design that often the human mind could not rival in ingenuity and sometimes studied success. For instance, the appendix becomes blocked by a stricture at its attached end, and being distended and loaded with deadly contents to the muzzle, smears itself over with a gluey coat and seeks to attach itself to some convenient outlet for its foul contents.

To evacuate into the peritoneal cavity is death to its owner, but if, by care, it can seal itself to another piece of bowel or the bladder, perhaps it can save its owner's life, and discharge into the outer world. It makes the effort!

Very often it succeeds, and we see such amusing accidents as an appendix discharging for years into the bladder, a miscarriage of justice, as it were, but designed—designed to save the patient. Who designed it? Not the owner of the organ. And what established habit of it, or its ancestors, taught it, or left it a heredity that came so opportunely in use? We stand appalled at the efficiency of Nature's methods at times, and yet she is a most bungling surgeon! Wonderful at repair, but a bungling surgeon.

And this idea brings us to consider the fatuous hope that lingers in the mind of all physicians, that what has happened once in repair will occur always; that reliance can be put upon the oft-witnessed success in ending this disease without operation. We may admire her reparative power, but must call her to account for her innumerable failures, and supplement her by the precise and successful methods of modern surgery.

Interest in the subject under discussion is doubly increased when doubtful cases bring the physician and surgeon in consultation; when at times a single symptom will turn the scales of doubt, one could often wish for unerring indications of the diseased appendix. One soon learns that pain over the appendix is not always present, or when present it may simulate other pains, so that an attack of gravel can be so like an appendical colic that only the discovery of a few blood cells in the sedimented secretion of the kidney will tell the presence of irritation of a small stone. Even the most characteristic local descending pain along the cord and bladder irritation may be simulated by adhesion of the appendix to the bladder surface.

The most complete experience of variations in symptoms is often required to differentiate between the disease in question and even so unlike a disease as typhoid fever, which in its onset is well imitated by it.

What has already been so much dwelt upon in the pictorial representation of its pathology, helps us here to understand why the mild pyæmic condition may simulate typhoid, and it becomes a deeper problem than usual to summon other resources, such as the leucocyte count of the blood, to determine the diagnosis.

This latter study of leucocytosis has grown to much importance in differential diagnosis. Typhoid fever can often be eliminated, because, if uncomplicated by ulceration, which is wanting in its early stage, there will be little or no increase in leucocyte development.

On the other hand, progressive leucocytosis in which 12,000, 15,000, 20,000 or more are found, indicates a progres in ordinary appendicitis to a certainty of abscess formation.

Again the sudden development of very marked leucocytosis, with diffused peritonitis, is an argument for the successful outcome of operative work, no matter how grave the appearance of general infection.

Many valuable observations are accumulating, so that we can get much help in diagnosis and prognosis from this newer aid.

It is not my purpose in this paper to enter into further scientific study of the many ramifications into which one might be led, though one may well have attention directed to the variety of hitherto unsuspected maladies of which this little organ is now recognized to be the frequent cause.

Its manner of hiding itself from suspicion is nowhere better shown than in conditions of profound pyæmia, into which a patient may be plunged after a day of appendix disturbance, followed by an absolutely painless condition when the physician is called on

the second or third day. Then, perhaps, the patient has a chill, and profound pyæmia with graver and graver symptoms follows. The physician is justifiably in doubt of a cause, on account, incredible as it may seem, of the absence of local signs, although a septic phlebitis of the larger veins adjacent to the appendix is present. Several times I have witnessed this local peritoneal anæsthesia masking the real cause of fatal pyæmia.

The resemblance of appendix disease to a large number of internal troubles would afford a chapter in surgery of great importance to the student.

The mimicry of other diseases by appendix disturbances is so accurate, at times, that the physician has to suspect this complication, not only in any case of supposed gall-stone pain, or that of movable kidney, or that associated with progressive dysmenorrhœa, but he must regard the ordinary colic, or the recurrent pains of indigestion to which the "chronic dyspeptic" is subject, as surely due, in many cases, to this cause.

It has been my hope to show that this problem is capable of such demonstration that the ever-recurring difference between the medical and surgical view of treatment should be reconciled.

Easy as it is to fall into the "waiting habit," the medical inaptitude for operation is not consistent with the seriousness of the subject.

Our greatest practical life-insurance companies recognize that a single attack of appenditis disqualifies from insurance for one or two years; recurrent attacks disqualify until the removal of the appendix.

I have shown: that inflammatory strictures are almost universally present, the foundation and cause of the subsequent disease; that while they are uniformly of slow growth the real mischief does not begin until occlusion occurs; that attacks are often cured by natural method; that a long respite does not mean a cure; that it is impossible to predicate a cure; that, unless the appendix is out, the disease is always "latent," when once it has begun.

In all studies of medical problems, truth spells itself out letter by letter, and it is many years before united opinion allows the knowledge of a topic to be incorporated in the surgical creed.

There will probably always be some diseases which will be beyond the successful management of the doctor. This subject, however, has now been lifted from the opprobrium of the past. It is one to which the cynicism of Matthew Arnold cannot now apply, when he says:

> Bring not to see me cease to live
> Some doctor, full of phrase and fame,
> To shake his sapient head, and give
> The ill he cannot cure, a name!

Lupus Vulgaris of Fifteen Years' Standing Successfully Treated and Cured by Exposure to X-Ray.—A. Everett Smith thus treated a patient of eighty years who was suffering from a lupus patch of the nose, inner canthus of the right eye, and inner thirds of the lids. A mask of sheet lead was made for the face, and a hole was cut for the diseased portion of the face, which was exposed every fifth day for about twenty minutes at a time, the diseased surface being placed about two inches from the light. About twelve treatments were given. Marked improvement appeared after the second treatment, which was not interrupted until the sore was entirely and completely healed. There was no burning from the light, nor were there any unpleasant symptoms except a slight headache and a crawling sensation in the sore with the first two treatments. The cicatrix has produced a slight ectropion by everting the inner end of the lower lid, and has drawn the upper down and in, but vision is normal.—*Buffalo Medical Journal*, January, 1901.

THE CAUSES OF FAILURE OF COMPENSATION IN DISEASES OF THE HEART.[1]

By MORRIS MANGES, A.M., M.D.,

PROFESSOR OF CLINICAL MEDICINE IN NEW YORK POLYCLINIC MEDICAL SCHOOL; VISITING PHYSICIAN TO MOUNT SINAI HOSPITAL.

To discuss the causes of the failure of compensation of the heart is by no means the unprofitable task it would at first glance appear, for the maintenance of life itself—and that too often during the critical periods of acute illnesses—may depend upon the proper appreciation of some of these causes. Too frequently we are unaware of the dangers which are lurking for patients with organic heart disease until some undue strains from acute illness, muscular overexertion, etc., warn us most emphatically of the real status. In pneumonia and nephritis death comes from the heart, and in all acute and chronic diseases the key of the situation lies in the myocardium. Another good reason for recognizing these causes is that from the information gained thereby we often obtain important therapeutic indications after digitalis and the other heart tonics will have lost their effects; so that we are thereby enabled indirectly to assist the enfeebled circulation by the relief of some of its collateral burdens.

Of still greater importance is this study to the thinking physician, since a clear conception of that ultimate crisis or crises to which all patients with organic cardiac diseases are finally doomed, may enable him to put off the evil day for a very long time; for compensation may endure for surprisingly long periods. Romberg mentions a case at the Leipsic clinic in which it was maintained for thirty-eight years, and Forler quotes another in which combined aortic and mitral lesions remained compensated for fifty-three years in spite of constant hard physical labor. It may not be amiss to mention that the average duration of compensation in one hundred and two cases, studied by Romberg, was seven years—a very good average when it is added that in one-third of these cases, from various causes, compensation was never established.

This discussion, however, is most difficult at the present time, since we are now going through a transition period in which many long accepted facts have been ruthlessly upset and have been replaced by others which, although apparently correct, have not yet been subjected to the crucial tests of time and experience. Indeed, the findings and the teachings of the new schools of Engelmann, Krehl, His, Romberg, and others are not universally accepted by all physiologists and pathologists. Many of the pioneer views of Traube and his school and the later work of Rosenbach still find numerous able defenders in spite of the radical claims of von Basch and his pupils, that there is no such process as that of compensation. The admirable work of Sherrington and other physiologists on the dynamics and physics of the heart and circulation, while they have shed much light upon many obscure phenomena, have not been grasped in their true significance. How far-reaching are these new views on cardiac physics may be comprehended from the admirable Lane lectures which have recently been published by Clifford Albutt. Likewise, perusal of von Leyden's address on the nervous mechanism and the autonomy of the heart muscle will afford much information on these most interesting subjects.

The consideration of these topics, although of very great importance to a proper and comprehensive conception of our subject, would require far more time than is at my disposal this evening. It need only be stated that the supreme importance of the muscle cells of the heart is clearly brought out, and that all else is of lesser significance.

[1] Read at a stated meeting of the New York Academy of Medicine, February 3, 1900.

Pathologists have also corroborated this, and it is, therefore, in the myocardium that we must look for the immediate relations of both compensation and decompensation, as the failure of compensation has been aptly termed by Romberg.

For a long time it was believed that the cause of decompensation lay in the undue distention of the myocardium, with subsequent fatty degeneration of the muscle cells. This view was upheld for a long time as the result of the influence of Stokes, Friedreich, Rosenstein, Strümpell, and others. Duclék was the first to doubt it, and it is now generally accepted by von Leyden, Strümpell, Fraentzel, Romberg, and others, that fatty degeneration is only of minor importance. This is also corroborated by Balint's experimental fatty degeneration in animals. Furthermore, the importance of an undue amount of residual blood being left behind in the ventricles or auricles as the result of valvular leakage is minimized by the observations of Roy and Adami, that the normal ventricles do not completely empty themselves during systole. Moderate leakage does not affect the healthy cardiac walls, and even undue distention may be successfully coped with by sound muscular fibres. But, as well described by Albutt, "the morbid results of dilatation lie not in the occasional stretching of a normal ventricle beyond the mean—this can be well met by the ordinary reserve energy together with the stimulus of excess loading—but they lie certainly in such a persistence of excess as to exhaust the organ. Nutrition being unequal to the persistent importunity, tone yields to prolonged, excessive tension, and although hypertrophy for a time may stave off the impending failure, a restoration somehow of normal conditions must come about if the heart is to regain its equilibrium. While it is essential then to a useful life that the heart shall be thus adaptable to fluctuations of demand, even to extreme demands, yet, on the other hand, over a long period of time the work ought not to exceed a certain mean, the amount of which varies for each individual; for Mosso and others have shown that the rate of muscular fatigue, whether skeletal or cardiac, varies in different individuals. In one person temporary dilatation of a ventricle under incidental stress is rapidly overcome; in another the limit of specific elasticity, insufficiently guarded by tone, is passed and strain irremediable may be established. The mutual play of tone versus dilatation is then of the first importance in all men; but tone varies in all men constitutionally, and in the individual with fluctuations of his health. Under no circumstances is tone more profoundly weakened than under the influence of the toxins of the infectious diseases."

That the normal heart can readily deal with acute dilatations has repeatedly been demonstrated in cases of overstrain from mountain-climbing, etc., the most striking examples of which have been the *x*-ray demonstrations of T. Schott. But the heart walls of patients who have had or have organic valvular disease are not normal, as has been demonstrated by Letulle in 1889, and much more elaborately in 1890 by Krehl and his school. Letulle showed that in hypertrophy the interstitial connective tissue increased as well as the muscle fibres; and he assumed that this proliferation of connective tissue caused a fatty degeneration of the muscle fibres. Tangl, in experimental hypertrophies in animals, showed that such an increase of connective tissue does not occur, but the importance of his findings is lessened by the findings in diseased human hearts, to be mentioned directly.

Krehl's elaborate studies with serial sections on hearts from patients with valvular disease threw a flood of light upon the relations of compensation and its failure. He found marked myocardial changes with increase and subsequent contraction of the connective tissue between the muscle fibres, with occasional focal destruction of the parenchyma. These changes were not found diffusely by Krehl, His, and Romberg, but they occurred only in small areas or foci and followed a necrosis of the muscular fibres; they were usually the result of some change in the nutrient blood-vessels, or they would follow inflammation of the endocardium or pericardium. In acute infectious diseases it appeared as if the acute interstitial inflammation resulted directly in the formation of new connective tissue.

Krehl, His, and Romberg studied the changes not alone in valvular diseases, but also in acute infectious diseases, pericarditis, heart strain, many intoxications, etc., and found these varying degrees of myocardial changes in foci in different parts of the heart.

Sack claimed that the auricles were most frequently involved, and regarded it as a compensatory phenomenon to strengthen their walls.

Dehio claimed that in addition there was also a diffuse process, a myofibrosis, in which there were diffuse new formations of connective tissue throughout the entire heart, which were interfascicular as well as interstitial. He claimed to have found this in the various cardiac lesions, and especially when the increased work of the heart had caused hypertrophy and dilatation of the entire organ or only a part of it. It was the stretching to which the hypertrophied muscles had been subjected which was the cause that the weakened muscular fibres gradually disappeared, and, as a reparatory act, connective tissue replaced them, the contractile powers of the muscle cells being replaced by the elastic force of connective tissue. This process was most marked in the auricles since their weak muscular walls could least stand dilatation. Thus the dilatation is the chief cause of the myofibrosis. He also admitted that diffuse connective tissue might occur in the acute infections. He also found myofibrosis in senile hearts, but believed that coronary arteriosclerosis was the chief cause.

Hochhaus and Reineke studied fourteen diseased hearts (senile, valvular, and acute and chronic infectious), but failed to find this diffuse myofibrosis in six cases of valvular disease. Their findings in these cases corroborated those of Krehl's school, that there are distinct focal changes in the parenchyma and interstitial connective tissue. They direct especial attention to the occurrence of focal changes, which being connected neither with the endo- or pericardium or blood-vessels, must have been the result of the acute infections (acute articular rheumatism, etc.) which caused the primary organic cardiac diseases. The foci were found in order of frequency in the left ventricle, right ventricle, and the auricles.

It is to be added that these views of Krehl and his school have been rejected by Bollinger, Rieser, and others.

Finally Ott claims to have found distinct changes in the cardiac ganglia in cardiac stasis and hypertrophy, and Bálint in experiments on animals found that the vagus was of importance in determining the time when decompensation set in after experimental destruction of the aortic valves.

To sum up briefly the various pathological conditions reported above, one is justified in stating that hearts which have been attacked by actual organic valvular disease from any cause no longer have an absolutely normal myocardium, since the latter has been involved in its parenchyma or interstitial tissue, or both, in various foci. Any defect in the valvular apparatus is compensated for a longer or shorter period by hypertrophy, which in turn is followed by changes in the parenchymatous muscle cells, or interstitial connective tissue, or both, or in the ganglionic cells or nerve fibres, or both, which may finally result in such

a weakening of the heart walls that the heart is no longer able to propel the blood in normal amounts, as needed by the system at large. The causes of this breakdown may be either one or both, the distention of the cavities which results from leakage at the valves, or it may be due to defective nutrition of the myocardium from arteriosclerosis, anæmia, chronic or acute intoxications, mechanical overstrain, or other causes, which will be discussed later on. But although this will explain why, *cæteris paribus*, a man with valvular disease will react more promptly and more markedly to a given insult, yet it is also demonstrated that if the nutrition of the heart is properly maintained, if the work which the heart must perform is properly regulated in amount and time, then these myocardial changes will in no way exert any deleterious action upon the individual, but may even be conservative to the heart as such, until the appearance of the arteriosclerotic changes, to which all hearts and all parts of the body must sooner or later succumb, since it must be distinctly understood that the reserve power of the hypertrophied heart is just as great as that of the normal organ; but if the causes of the hypertrophy are still active, then the constant call on its reserve energy, as already stated above, will result in the diminution of the amount at its disposal. Finally, while it is admitted that a hypertrophied heart is more liable to arteriosclerosis of the coronaries and chronic myocarditis, yet with proper care for the nutrition of the body at large and the work of the heart this may be controlled for a long time.

Viewed from the clinical side it may be said that the failure of compensation is not a clinical entity, nor does it represent any definite etiological or anatomical factors; but, to paraphrase Romberg, it represents the clinical course of various anatomical, dynamic, and functional influences which are always occurring in various combination, since it is not always the result of one cause acting alone, but very frequently of several acting in combination or succession. It will be found that these factors either produce dilatation of the chambers of the heart or impair the nutrition of its walls.

The most important of these causes may be grouped as follows, modifying the classification of Osler:

1. Failure of general nutrition of the body.
2. Disturbance of local nutrition of the heart.
3. Increased work of the heart.
4. Functional cardiac disorder.
5. Effects of improper treatment.

Failure of general nutrition is in its final results closely allied to the second group of local disturbances of nutrition, yet it is important to consider each separately on account of the differences in the etiological factors.

I. Of the general causes anæmia is one of the most potent and common; it may result from poverty with its endless exposure, poor food, etc.; or it may be associated with obesity; or, far more commonly, decompensation may follow severe reduction cures. Many a compensation is shattered at Carlsbad and other resorts under the so-called guidance of physicians. How many more are wrecked by the patient's own efforts in Banting, thyroid medication, etc.! Far too many paunches are flattened, livers shrunken, and gall bladders cleansed, dyspepsias cured, vain women's figures restored to youthful lines and suppleness with the high sacrifice of cardiac compensation. Small wonder, then, that Carlsbad physicians are now sending their patients to Nauheim for the after-cure!

The chronic infections and intoxications, such as result from chronic nephritis, severe digestive disorders, tuberculosis, metallic poisons, are also important factors; gout, diabetes, and similar constitutional disorders are also potent causes in slowly producing changes in nutrition, which are finally indelibly impressed upon the heart.

More rapid in action are the acute infections, such as acute articular rheumatism, diphtheria, scarlet fever, typhoid fever, pneumonia, influenza, sepsis, etc. The most important of these are influenza in persons over forty-five years of age, with its marked general depression, and acute articular rheumatism. The latter acts in a twofold way, for besides the general effects of all infectious disease, which are already referred to above in Krehl's findings that the so-called "Herzschwiele" results directly from the acute infections, each successive attack of acute rheumatism may inflict further damage upon the structure of the heart. It is also to be noted that Schroetter and others believe that in some of the acute infections there are additional central disturbances which affect the vasomotor system, and thus indirectly influence the heart.

II. Disturbances of local nutrition of the heart. Of these causes coronary arteriosclerosis is by far the most important and far-reaching in its action. Insidious in its onset, silent in its slowly progressive action, it is most destructive in its effects upon the myocardium and brings to light any defects in this structure; in consequence the reserve power is so diminished that the heart can no longer respond to the calls which are made upon it, and hence, unless the patient has been warned about his condition, he is apt to subject the organ to strains which may cause irreparable damage.

As the arteriosclerotic process is rarely limited to the coronary arteries, but is usually manifested in the aorta and the other arteries, the effects of atheroma of the aortic valves, arch of the aorta, chronic nephritis, are added to the burdens of the heart.

The other effects of chronic endocarditis and pericarditis are self-evident, and need no further discussion here. Of chronic myocarditis it need only be added that the special localization of the areas of degeneration may precipitate the occurrence of decompensation, as for instance when the auricles are especially involved, or the apex of the left ventricle, the latter being particularly marked in aortic regurgitation.

Hearts with valvular disease and hypertrophy are especially liable to these disturbances of nutrition, and respond to them more markedly since, as has already been stated, definite changes are established in the heart structure by the primary cause of the lesion.

III. Increased work of the heart. This may arise from a variety of causes, and may either be of transitory duration or may last for an indefinite period. It plays an important rôle in the causation of decompensation, and not infrequently is the means of telling a man that the condition of his heart is not what it ought to be.

Muscular overstrain, due to overlifting, undue mountain climbing, bicycle riding, and prolonged and violent athletic exercises, has been so fully discussed during recent years that it does not require much more than mention here. The damage inflicted by distended auricles and ventricles, ruptured heart valves, etc., may at first be equalized by the reserve force of the heart; but later on, if the insult is repeated too often, or if the structure of the myocardium has suffered, it can no longer do so and irreparable dilatation may result. It is to be noted that most of the changes occur in the right auricle and ventricle. If people would exercise with their brains as well as their muscles, as suggested by Schroetter, such cases would be less common than they are.

Parturition in women with valvular disease is closely allied to this class of cases, and the increased work thrown upon the heart has not infrequently led to an acute failure of compensation, which was fatal

in a few hours or days; or there may be more or less complete recovery from the decompensation.

The work of the heart is also increased in many other conditions, among which may be mentioned pericardial adhesions, renal diseases and arteriosclerosis in general, obesity, chronic bronchitis and emphysema, large pleuritic effusions, pulmonary infarctions, and other conditions which increase the work imposed upon the right heart.

More tangible and under more direct control are the effects of excesses in food, alcoholic stimulants, tobacco, etc. It will be observed that many of the above factors act injuriously in more than one way, and deserve the especial attention of physicians in the prophylaxis of decompensation.

IV. Purely functional cardiac disorders as causes of decompensation are rare; extreme mental emotions, such as fright, marked mental excitement or emotions, prolonged worry, may act in this way on account of the enormous rise in the arterial pressure which, according to Romberg, may follow them when they occur in persons with weak hearts. Deaths from broken hearts must be accepted as an actuality. These cases are usually due to idiopathic dilatation. "In some the condition is acute and the patient has dyspnœa, slight cyanosis, cough, and great cardiac distress. Death may occur in a few days, or dropsy may supervene, and the case become chronic. Delafield has reported an interesting series of cases of this group" (Osler). Schroetter and others have also reported cases of this kind.

V. As a separate group may be placed those unfortunate cases—alas! too large in number—in which the failure of compensation is not due to disease but to the physician or the patient himself. I refer to the abuse and improper administration of cardiac drugs by doctors to whom the presence of a murmur is the signal for the prompt and heroic administration of digitalis, etc. The constant and uncalled-for demands upon the reserve energies of the heart by such means not infrequently precipitate cardiac failure. At present the abuse of the Nauheim method, Zander exercises, etc., in the hands of many physicians, is doing more harm than good in destroying compensation rather than in improving the condition of the heart. Following fads is one thing; judicious employment of these rational methods after comprehending their underlying principles is another. This is not theoretical, since I have seen such cases.

Lack of time has induced me to omit the narration of any special cases to illustrate these various causes of decompensation. I trust, however, that the underlying causes have been made sufficiently clear. As a corollary it follows that the treatment of heart diseases consists in much more than the observation of heart murmurs; that the heart muscle is the important factor; and that in the treatment of failure of compensation broad and comprehensive views, which include not only the condition of the heart itself but of the entire body, can alone do the greatest amount of good to this class of patients.

Regular Breathing in Beginning Narcosis.—C. Hoffmann emphasizes the importance of securing regular respiration while the first stages of anæsthesia are progressing. Quiet and kindly encouragement of the patient are of great value, and the direction to count out loud often accomplishes the purpose, but a still more efficacious method is to have the patient begin with some number having three figures or more and then count backward. The amount of mental concentration required to do this, as well as the act of pronunciation, insures deep regular respiration in almost every case.—*Centralblatt f. Chirurgie*, January 19, 1901.

STRABISMUS AND ITS MANAGEMENT.[1]

By J. H. WOODWARD, B.S., M.D.,
NEW YORK.

Every physician must advise strabismic patients from time to time respecting the management of their condition. For the guidance in this regard of those who need it, my purpose will be to outline the subject as simply as possible, divesting it of technicalities and stripping it of abstruse considerations, which are of interest to ophthalmologists alone, and yet making it sufficiently complete in detail to attain the object in view.

Strabismus is an abnormality of the eyes in which the lines of sight do not meet at the object upon which the gaze is fixed. When the lines of sight meet between the observer and the point observed, the condition is known as convergent strabismus. When the lines of sight either do not meet at all, or meet beyond the point observed, the condition is called divergent strabismus. The line of sight of the deviating eye may rise above, or it may sink below, the observed point. In the former condition we speak of an upward strabismus, while in the latter we speak of a downward strabismus. Combinations of convergent and divergent strabismus with upward or downward strabismus occur. Of these combinations the most often observed is that in which the eye turns upward and inward.

In deference to custom we are all using a terminology in discussing this subject that ought to be considered obsolete. The terminology proposed by Stevens some years ago leaves nothing to be desired, and it should supplant the older and less scientific terms. Thus heterotropia signifies a deviation of any kind; esotropia signifies a deviation toward the nose; exotropia signifies a deviation toward the temple; hypertropia signifies a deviation of one of the lines of sight above the observed object, while hypotropia signifies that one of the lines of sight falls below the point of fixation.

From the etiological point of view cases of heterotropia are subdivided into two classes, namely, cases of paralytic strabismus, and cases of non-paralytic strabismus. Among the examples of paralytic strabismus there are cases in which the suspension of function is complete, and there are others in which it is incomplete. Non-paralytic deviations may be alternating, in which case either eye may fix its gaze upon the object looked at; or the strabismus may be unilateral and constantly confined to the same eye.

Paralytic strabismus is sequential to a pathological or a traumatic lesion of the ocular muscle itself, or of its motor nerve, or of the origin of the nerve. When the paralysis depends upon a lesion of the muscular tissue, the cause is most frequently a contusion, or a laceration, or an incised wound of the orbit. Rheumatism is the most common condition of the ocular muscles themselves, resulting in suspension of their function. And of these cases, rheumatic paralysis of an external rectus is observed most frequently.

The function of the motor nerve may be suspended by penetrating traumatisms of the orbit and by fractures of the base of the skull. Pathological changes in the membranes covering the base of the brain, and diseases of the bones composing the base of the skull, also may interrupt the function of the motor nerves of the eyeball. A large percentage of the lesions are syphilitic, and, in general, a provisional diagnosis of that disease may be entertained as a working hypothesis. Other diseases of the meninges and cranial bones are observed as etiological factors in paralytic strabismus. Among them may be mentioned as especially

[1] Read before the New York State Medical Association at its seventeenth annual meeting, October 16, 17, and 18, 1900.

important pachymeningitis, leptomeningitis, tuberculous meningitis, cerebral tumors, and cranial osteomata.

The central lesions which destroy the function of the ocular muscles are also frequently of syphilitic origin. Thrombosis, embolism, and rupture of the cerebral blood-vessels often cause paralysis of ocular muscles, usually in conjunction with paralysis of other parts of the body.

Paralytic strabismus occurs as a congenital defect. In certain cases this paralysis may have been due to traumatisms of the orbit sustained during delivery. In other cases, however, there can be no reasonable doubt that the function of the affected muscle had been arrested *in utero*.

Ocular paralyses are due also to acute systemic diseases, especially typhoid fever. Diphtheria often gives rise to paralysis of the accommodation, but it is rarely followed by paralysis of the muscles that rotate the eyeball.

The symptoms of paralytic strabismus may be enumerated in the order in which they attract attention; thus, confusion of sight, vertigo, double vision, impairment of the sense of perspective, uncertainty of gait while both eyes are open, deviation of one of the lines of sight from the object observed, restricted movement of the eye, confused feelings in the head, and sometimes headache. Their onset is sudden, and they are fully developed early. The most characteristic and troublesome symptoms is the diplopia.

The pathology of non-paralytic strabismus is still less simple. In a considerable number of cases hypermetropia, myopia, or astigmatism is the predisposing condition. It occurs as a sequence of ulceration of the cornea, even during the stage of inflammation and photophobia. It is induced by opacities of the media of the eye, and by other conditions which reduce the visual power of one of the eyes below that of the other. Its beginning is often observed during or immediately following an attack of whooping-cough. We find, moreover, that after the hypermetropia, myopia, or astigmatism has been corrected by properly fitted glasses, even in many cases which were primarily due to those errors of refraction, the squint still persists. Then the persistence of the deviation will be the result of contracture of the overacting muscle and its investing capsule, or to enfeeblement of the antagonistic muscle through stretching of its fibres, or to both conditions combined.

These are the common apparent causes of non-paralytic strabismus. It is not pretended that this *résumé* may be regarded as anything more than a sufficient explanation of the commonest phenomena, for the guidance of those who are not especially interested in the subject. Further discussion of it would involve technicalities which the limits of the paper do not permit me to inflict upon you, even were I desirous of doing so.

The principal symptom of non-paralytic strabismus is deviation of the line of sight of the squinting eye away from the object upon which the gaze is fixed. This constitutes a deformity, which, in marked divergent strabismus, may be almost hideous. And yet, however great the deviation, the movements of each eye separately are not restricted in any direction in the same sense as they are in paralytic cases. When the squint is alternating, the visual power of both eyes is about equal; when it is fixed, the squinting eye is always more or less amblyopic, and the ophthalmoscope reveals no reason why its visual power is not normal, or why it may not be raised to normal by lenses. As yet I have not seen a case of non-paralytic strabismus in which the patient complained of double vision. Indeed, it is often extremely difficult to make the patients see double. They do not use both eyes simultaneously. The images that are photographed upon either the central or the peripheral portions of the retina of the deviating eye are not consciously perceived without an effort of the will. And the longer the period through which the squint is permitted to exist the less sensitive to visual impressions does the eye become. On the other hand, if the heterotropia be corrected and proper glasses worn, considerable acuteness of sight may be gradually restored to many of these eyes.

A differential diagnosis of paralytic from non-paralytic heterotropia does not present any important difficulties. It is evident that the sudden appearance of annoying double vision is the most significant indication of paralysis of the ocular muscles. In non-paralytic cases, patients do not complain of diplopia, although in certain instances it may be proven to exist, notwithstanding that the patients are unconscious of its presence. Restriction of motion toward the side of the paralyzed muscle is the second important differential factor. There is some restriction of movement in the direction opposite to the deviation of the squinting eye in very marked non-paralytic squint. But in paralytic cases it is the almost invariable rule that limitation of the excursions of the eyeball is so distinct as to suggest paralysis immediately. Moreover, the sudden onset of confusion of sight, the sudden impairment of the sense of perspective, the sudden inability to walk without closing an eye, or turning the head so as to suppress the false image, complete the differential diagnosis of paralytic from non-paralytic strabismus.

From a psychological point of view the significance of paralytic heterotropia is much greater than that of the non-paralytic variety. It is quite as important from a sociological standpoint; for the greater number of patients are adults, engaged in useful and profitable occupations, whose ability to continue their pursuits with their customary vigor is either suspended or greatly impaired by the ocular defect. Furthermore, life is often endangered by the lesions upon which the paralysis depends. In every case a favorable prognosis as regards permanent and complete recovery from the squint should be made with great reserve.

In non-paralytic heterotropia two factors are especially important to the patient: (1) the existence of deformity that distinguishes him from his associates, and (2) the exclusion of one of his eyes from participation in binocular vision. Inasmuch as these squints develop in childhood, their significance from a psychological and sociological standpoint should not be overlooked, for children are made sensitive, shy, and timid by the attention which unthinking adults and barbarous playmates bestow upon their deformity. Others become morose, resentful, and suspicious. These facts are common to both sexes. The cosmetic importance of normal and attractive eyes to the female needs no elaboration. These deformities, then, may prove to be serious handicaps in the struggle for existence, a disadvantage that is intensified by loss of binocular vision. If we comprehend, therefore, the significance of these drawbacks to individuals afflicted with strabismus, we must understand that their condition materially diminishes their importance as members of society.

A great deal of misapprehension respecting the relationship of non-paralytic strabismus to "eye strain" has been revealed in ophthalmological literature even within recent dates. From what has already been said it must be clear to every one that "eye strain" cannot be due to non-paralytic heterotropia, for in such deviations there is no effort of binocular vision. In cases of paralytic heterotropia, when the paralysis is not complete, instinctive efforts to suppress diplopia develop the symptoms of muscular asthenopia; but

when the paralysis is complete, I would not classify the symptoms in any case as belonging to that category.

In the management of paralytic strabismus a thorough determination of the extent of the paralysis and a probable diagnosis of the underlying lesion must be made at the very outset. I submit to you the rational proposition that this may be accomplished only by those who are conversant with cerebral pathology and the intricacies of ophthalmology as well. A complete diagnosis is essential, for there are cases which are hopeless from the beginning, and there are others which may be relieved by the application of proper measures. In syphilitic cases anti-syphilitic remedies, in rheumatic cases anti-rheumatic remedies, are indicated. Sometimes medicines that diminish the blood-pressure must be prescribed. In other words, the internal therapeutics of ocular paralyses depends upon the nature of the lesion and the extent of its manifestations.

Locally, we are compelled to exclude the deviating eye from the act of vision, in order to suppress the diplopia. When the paralysis is confined to one or two muscles, and especially if it be incomplete, prisms, stereoscopic exercises, and electrical stimulation at the proper time, are indicated. Later, if the paralysis be confined to a single muscle, and should it prove to be incurable, advancement of the paralyzed muscle may be considered. The operation is most likely to succeed in cases of partial paralysis; but it should be recollected that diplopia from ocular paralysis is a very difficult symptom to subdue.

The management of non-paralytic strabismus consists, in the first place, in a proper correction of the errors of refraction of both eyes. Atropine should be used until the accommodation is completely paralyzed, and all the resources of ophthalmology should be brought to bear to insure a perfect correction of the refraction. Were it not for the fact that many physicians are in the habit of sending patients to opticians to have their glasses fitted, it would be superfluous to comment further upon this point. It is incomprehensible that an intelligent and conscientious physician should give such advice to one of his patients. But it is done regularly by a very large number of our colleagues; more frequently, I believe, in large cities than in smaller communities. What criticism would be heaped upon ophthalmologists if, in a perfectly comparable and precisely as reasonable a way, they were to advise patients to consult a druggist for their various ailments! You would struggle to find words suitable for the expression of your indignation, I am sure. The welfare of thousands of patients depends more upon the adjustment of correct lenses to their eyes by a trained ophthalmologist who understands pathology as well as optics, than upon all the medicines in all the drug shops in this city.

In a comparatively small number of cases the constant use of proper lenses will subdue the heterotropia. In a certain percentage of cases relief may be obtained by the addition of exercises with the stereoscope to the treatment. In the majority of cases one or more operations will be required to complete the cure. When the strabismus is alternating and marked, both eyes must, as a rule, be operated upon. When the strabismus is unilateral, operation upon the deviating eye alone will usually prove sufficient. Division of an ocular muscle is, indeed, a small matter which any surgeon can accomplish without much effort. But that is not what we mean nowadays by the treatment of strabismus. The doctrine that, given convergent squint, for example, we must divide one internal rectus, and if that does not cure we must then divide the other, has resulted in so many examples of divergence that the tradition of those days of heroic ignorance still carries distrust of ophthalmic surgery to the minds of many patients and physicians. The truth is, each case is a problem by itself, to be studied with care and solved with cautious deliberation and sound judgment. In general terms we have to deal, on the one hand, with an overacting and often contractured muscle, and on the other with an overstretched and enfeebled muscle. The principle that ought to control operative interference is that we should weaken the one by judicious tenotomy, and strengthen the other by advancement of its insertion. Upward deviations, so often overlooked in convergent strabismus, must be corrected by "graduated" tenotomies, in order that the object sought may be attained.

The ideal result consists not only in reduction of the apparent squint, but in the establishment of normal binocular excursions of the eyeballs, and in restoration of binocular vision. It is readily comprehensible that such an ideal may not be attained by a *coup de théâtre*. That it may be attained by painstaking endeavor is one of the many achievements of modern ophthalmology.

Treatment of heterotropia should be inaugurated as soon as the child is old enough to wear glasses. Even operative interference need not be postponed, as some advise, until the sixth or seventh year; for it is frequently advantageous to begin such work at an earlier age. On the other hand, the fact that strabismus has persisted twenty or more years does not contraindicate an operation for its correction.

In conclusion, it may be said that heterotropia is vastly more difficult to deal with satisfactorily than are most cases of cataract, notwithstanding that the truth of the proposition depends upon one's conception of what constitutes a good result. Operations for heterotropia should not be undertaken by one who is not familiar with the anatomy, physiology, and pathology of the visual apparatus; and only those operators whose technique is characterized by scrupulous surgical cleanliness should be permitted to engage in such work.

58 West Fortieth Street.

Pathology of Puerperal Sepsis.—Alfred Bass (*Centralblatt für die Grenzgebiete der Medizin und Chirurgie*, November 22, 1900) draws the following conclusions: (1) The uterine cavity of healthy, unexamined pregnant women, and in most cases that of healthy post-partum patients, is free from pathogenic germs. (2) The question as to whether the vagina of healthy, unexamined, and non-irrigated pregnant women and post-partum cases is free from pathogenic bacteria, cannot at present be definitely answered, even though a series of observations point in this direction. (3) Auto-infection in any given case must be diagnosed only when every possibility of external infection has been excluded; then auto-infection, Ahlfeld's view notwithstanding, will be found as a very rare occurrence. (4) The following bacteria have been found as causes of puerperal sepsis: streptococcus pyogenes, staphylococcus pyogenes aureus and albus, bacterium coli commune, pneumococcus, typhoid and diphtheria bacilli, bacillus aerogenes capsulatus, and vibrion septique. (5) The portal of infection is most frequently the endometrium, especially the placental site, both of which are reached by the direct introduction as well as the rapid growth of the bacteria. (6) The way of infection is lymphatic or circulatory, seldom both at the same time. (7) A positive clinical differentiation of the various bacterial forms cannot be determined, though the anaërobic infection runs a milder and more favorable course. (8) The blood examination, with the exception of bacteriæmia, shows nothing characteristic for puerperal sepsis.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, February 16, 1901.

STATE BOARD OF CHARITIES.

THERE is a bill before the legislature of this State which has for its object the abolition of the present State board of charities of twelve unpaid members and the substitution of one paid commissioner, with whom are to be associated two State officials selected by the governor. As the charities of the State have for the most part been organized under the advice and direction of the medical profession, and as the State board of charities was created with the aid of our profession to provide adequate State supervision of these institutions, the radical changes in the composition of the State board, which this bill contemplates, deserve our serious consideration. The reasons given for the proposed change are threefold, viz.: (1) the board is too large; (2) one commissioner can perform the duties of the board; (3) economy. These propositions can now be discussed intelligently, for we have before us the results of thirty-four years' work of the board. Let us first trace the organization of the present board. The plan is that of the famous English commission, which has done so much to elevate the charities of that country during the last half century, viz., an unpaid body of commissioners, distinguished for their philanthropy, having the power of visitation, inspection, and supervision. The State board at first consisted of one commissioner from each judicial district of the State, eight in number; subsequently, three additional members were appointed from New York City and one from Brooklyn, making the board consist, as at present, of twelve members. The advantages of an unpaid board of large size are threefold. First, the politician never seeks a position that has neither salary nor patronage; hence the board is entirely removed from the sphere of political influence. Second, a large board permits the different religious denominations interested in charitable institutions to be represented in its councils; Protestants, Catholics, and Jews are represented in the present board. Third, a large board secures the appointment of persons of different occupations who are specially adapted for the various duties devolving upon the board; in the present board there are four distinguished lawyers, one of whom was a former attorney-general, two physicians eminent in their profession, five business men of large experience, and one woman who has long devoted herself to the visitation of the charities of New York. The history of the board during the thirty-four years of its existence shows that its membership has always been specially adapted to its work, and at no time has there been a taint of politics or religious influence in any of its acts. The advantage to the board in having among its members two physicians, skilled in the management of institutions devoted to the care of the sick, is incalculable. Scarcely less important is the advice of its legal members, as the board is required to make rules and regulations which have the force of law. The value of the experience of business men and of a woman commissioner in the inspections required cannot be doubted.

It is alleged, second, that a single commissioner can perform the duties required of the board. We can best judge of the truth of that statement by reference to the duties imposed on the board by the constitution and the statutes. The constitution provides that the board "shall visit and inspect all institutions, whether State, county, municipal, incorporated or not incorporated, which are of a charitable, eleemosynary, correctional, or reformatory character," excepting prisons and institutions for the insane. The legislature in the State charities law provides that the board shall not only visit and inspect, but shall "maintain a general supervision" of these institutions. In addition, the law requires that the board shall aid in securing their just, humane, and economic administration; advise the officers in the performance of their duties; secure the erection of suitable buildings; approve or disapprove the organization and incorporation of all charitable institutions; investigate the management of charitable institutions as to the conduct and efficiency of the officers and the care and relief of the inmates; secure the best sanitary condition of buildings and grounds, and advise measures for the protection and preservation of the health of inmates; secure the establishment of such industrial, educational, and moral training in institutions having the care of children as is best suited to the needs of the inmates; investigate the condition of the poor seeking public aid, and advise measures for their relief; administer the laws providing for the care, support, and removal of State and alien poor, the support of Indian poor; collect statistical information in respect to the property, receipts, and expenditures of all institutions, and the number and condition of the inmates and of the poor receiving public relief. Investigations are almost constantly being made by individual commissioners in their districts of complaints of abuses in institutions under their immediate supervision. On such occasions the commissioner is empowered by law to issue compulsory process for the attendance of witnesses, to administer oaths and examine persons under oath, and to exercise the same powers in respect to such proceeding as referees appointed by the supreme court. The State board must approve of the incorporation of every institution which is of a charitable character; before the board takes action the commissioner of the district where the institution is to be located makes a thorough investigation of all the circumstances connected with the pro-

posed incorporation, and reports the facts to the board as the basis of its action. Finally, the recent dispensary act places all the dispensaries of the State under rules and regulations made by the State board, and requires that board to enforce them.

Can a single commissioner perform these duties as satisfactorily as a board of twelve members located in the several judicial districts of the State? This question must be left to the judgment of our legislators.

It is alleged, third, that a board with a single paid commissioner will be more economical than a large unpaid board. This is a proposition depending upon so many conditions and contingencies, such as the number and qualifications of employees, the frequency of visitation and inspections of institutions, etc., that an intelligent statement cannot be made. It cannot be doubted, however, that if the single commissioner is to do the work of the twelve commissioners, as that work is detailed in the annual reports of the board, the proposition is preposterous. He not only cannot do the amount of work done by the board, but being a man bred to a particular calling he cannot do the variety of work which is required. A large percentage of the charitable institutions should be often visited by a medical commissioner; many of the investigations should be conducted by a legal commissioner; certain examinations should be made by a woman commissioner; the business affairs of institutions should be investigated by business commissioners. If in place of the word economy we substitute the word efficiency, there can be no hesitation in deciding in favor of the large commission.

While, therefore, we are led to the conclusion that the reasons given for changing the large unpaid board to a single paid commissioner with two associates, already occupied with other official duties entirely foreign to those of supervising charitable institutions, are fallacious and ought not to prevail with the legislature, it is not difficult to detect dangers to our charities lurking in a board of supervision made up as provided in the bill before the legislature. Such a board cannot take that broad and comprehensive view required of a body whose duty is to supervise the management of institutions having a great variety of religious, social, educational, and financial interests. Nor can it have that freedom from the contamination of political partisanship so essential to the moral power which an independent board like the present exercises.

We trust the legislature will be governed in its action in this matter by the considerations which led the constitutional convention to make a State board of charities a permanent feature of our State government; its committee on charitable institutions made an exhaustive study of our system of administration of charity and of its supervision by the State board. In its final report of the clauses of the constitution relating to charitable institutions the committee enlarged upon the necessity of a closer State supervision, owing to their enormous increase and the vast amounts of money which they annually expended. The committee, therefore, not only greatly enlarged the powers and duties of the board, but recommended that it be made a permanent feature of the State administration, and that the existing board should be continued. In the discussion of the report which followed, the president, Hon. Joseph H. Choate, urged the adoption of the section reported, and stated that State supervision of charitable institutions should be so thorough that every dollar of money contributed to their support could be traced to its ultimate destination. The report was adopted by the convention and a State board of charities became a constitutional organization, and the existing board was continued with greatly increased powers and responsibilities. As there is no allegation that the body thus constituted has not, in every respect, performed wisely and promptly all the duties imposed upon it, both by the constitution and by the laws subsequently enacted, we urge the present legislature to proceed with great caution in the adoption of the proposed plan of reorganizing the State board of charities.

THE HEALTH OF HAVANA.

The report of Major W. C. Gorgas, the chief sanitary officer of Havana, respecting the health of that town of somewhat evil repute, is decidedly encouraging. In the Medical Record asseveration has frequently been made that, given thorough sanitary methods carried out on American lines and supervised by American experts, in the course of time Havana, from being regarded as perhaps the most-to-be-dreaded city in the world, will be looked upon in much the same light by the inhabitants of this hemisphere as are Nice and other towns on the Mediterranean coast by the people of Europe. Those persons from the United States who have occasion to visit Havana on pleasure or business, undertake the trip, as a rule, with a considerable degree of fear and trembling. Yellow fever is ever present in their minds. The report alluded to above will tend to allay much of this alarm, and the steady decrease in the death rate will assist in imparting a well-grounded confidence in the efforts of the sanitary staff to purify Havana. Although it is true that in 1900 yellow fever claimed three hundred and ten victims, while in the previous year (the first of American occupation) but one hundred and three succumbed to the disease, yet at the same time the fact must be taken into consideration that even in 1900 seven other maladies ranked above yellow fever from the standpoint of mortality. And further than this, Major Gorgas states that the death rate of Havana was less in 1900 than in any year in the preceding decade. In 1896 no fewer than 1,282 of its inhabitants died of yellow fever, the highest number in the eleven years of which notice is taken in the report. The list of deaths from various diseases is as follows: 851 from tuberculosis, 506 from diarrhœa and enteritis, 443 from organic heart troubles, 393 from meningitis, 357 from diseases of the arteries, 344 from malaria, and 319 from pneumonia. Typhoid, diphtheria, and smallpox figured inconspicuously as causes of death. During the past year the total cases of yellow fever numbered 1,244, of which 920 occurred

among Spaniards and 235 among Americans. Twenty-five per cent. of the Spaniards died, and 14.89 of the Americans—a result which may be put down to three causes: the superior stamina of the Americans, the better conditions under which they lived, and the more efficient nursing which the majority of them were able to procure. The Spaniards, who have been flocking into Havana at the rate of 2,500 per month, and who have suffered most severely from yellow fever, were for the most part a poverty-stricken, ill fed class, and consequently ill-adapted to withstand the attacks of the disease. The important fact stands out prominently that there were fewer deaths in Havana than in any of the past ten years. The increase of yellow fever in the year 1900 over that of the previous one may be indisputably attributed to the large Spanish immigration of the afore-mentioned period. The measures taken by the sanitary department of Havana and recorded in the report will convey a good idea of the magnitude of the task and of the energy displayed by its members. Of the 857 occupied blocks making up the city, 452 have had one or more cases of yellow fever in them. In these blocks there are 26,701 houses, of these 885 have shown evidence of infection by having had one or more cases. Of the 885 infected houses, 694 were successfully disinfected by one disinfection, as shown by the fact that they had only one case, 139 required two disinfections; that is, of the 885 infected houses all but 61 were freed from yellow fever after the second disinfection. That these exertions have met with their due reward is evidenced by the decreased death rate, which in 1900 was 24.40, while the lowest of the preceding ten years, that of 1893, was 30.66, and for the first year of American occupation, 1899, it was 33.67. In perusing the report, it will be observed that in the list of deaths by sex and nationalities, the large proportion of deaths among the white males is very noticeable. The explanation of this is that many of the inhabitants of Havana are foreigners, these foreigners being almost entirely males, which causes the male population of Havana to be greatly in excess of the female. Other interesting points contained in the report are that young persons are more susceptible to yellow fever than those of mature age; that the highest death percentages among the aliens were 47.05 for the Italians and 40 for the British, the American percentage being only 14.89; that native Cubans are not by any means wholly immune, but that negroes appear to be almost entirely so. Major Gorgas is fully entitled to the self-gratulatory remark that the work of his department has been eminently successful. A few more years of such work will undoubtedly make of Havana a city as salubrious as it is beautiful.

Atlantic City (N. J.) Medical Society.—At the annual meeting held February 6th, the following officers were elected for the ensuing year: *President*, Dr. Theodore Boysen, of Egg Harbor City; *Vice-President*, Dr. W. K. Darnall; *Secretary and Treasurer*, Dr. Theodore Senseman; *Reporter*, Dr. A. B. Shimer.

News of the Week.

Despatch of More Nurses to South Africa.—The secretary of state for war of Great Britain has announced that thirty nursing sisters of the Army Nursing Service Reserve are proceeding to South Africa.

Infant Mortality in France.—Attention is being drawn in France to the very serious infant mortality. The industrial and mining districts appear to suffer most, and a connection between the numerous deaths and the large consumption of alcohol is drawn.

Against Compulsory Vaccination.—A bill has again been introduced into the Pennsylvania legislature for the repeal of an act providing that all pupils who wish to enter the public schools must produce the certificate of a physician, stating that they have been successfully vaccinated. The Philadelphia bureau of health is opposed to the repeal and in favor of compulsory vaccination—as, in fact, are all others competent to form an unprejudiced opinion.

College of Physicians of Philadelphia.—At a stated meeting held February 6th, Dr. John Chalmers Da Costa read "A Memoir of the Late Sir James Paget." Dr. J. F. Schamberg and Dr. F. J. Frank Wallis exhibited wax models of cutaneous diseases, and made remarks upon the uses of wax models and their preparation. Dr. B. Alexander Randall read a paper entitled "Notes on Fifty Operations for Otitic Extradural Abscess." Dr. John B. Roberts presented a cast and a skiagraph from a case of so-called Smith's fracture of the radius, and a skiagraph from a case of so-called Bennett's fracture of the metacarpal bone of the thumb or "stave of the thumb." Dr. John H. Musser and Dr. H. R. Wharton read a paper entitled "Perforated Ulcer of the Stomach; Operation; Recovery."

Interesting Excavations.—Twenty-seven years ago Dr. Rudolph Herzog, of Tübingen, undertook excavations in the island of Cos, with a view of finding the temple of Æsculapius. At a depth of 80 cm. (thirty-two inches) he came upon a mosaic flooring which represented Orpheus charming the wild beasts. At a depth of 2.5 m. (nearly eight feet) in the neighborhood of the Church of Saint Anna he found two columns, and not far from them the remains of an aqueduct and a small statue of a young man. Great importance is attached to Dr. Herzog's discovery of the supposed temple of Æsculapius. The excavations are still in progress, and it is hoped that many antiquities will be unearthed.

Serum Mystery in Milan.—A curious case of poisonous serum is reported from Milan. Eight persons suffering from diphtheria died of tetanus after having undergone the orrhotherapic treatment. The authorities immediately closed the institute and prohibited the use of the serum throughout all Italy, pending an investigation by the health board of Milan and the council of hygiene in Rome. The directors of the institute in Milan called in all the flasks of serum which it had sent out, and destroyed all the materials for the different serums in process of

preparation. The case puzzles the professors. They don't know yet whether the serum was contaminated by the presence of microbes of tetanus, or whether by some unfortunate accident anti-tetanic serum was used in the diphtheria cases with fatal effect.

Percentage of Insanity Caused by Religion.—The report of the superintendent of the Central Hospital for the Insane, Indianapolis, has recently been submitted to the governor. The superintendent classifies the causes which led to the insanity of the persons committed during the year, and of the five hundred and seven nearly ten per cent. were made insane by reason of religious excitement. The report says that none of the latter was affected by hereditary insanity.

Seats for Female Shop Assistants.—The new French law as to the provision of seats for shop assistants came into force on January 1st. All shops and similar places where goods are offered for sale by a female staff must be provided in each room with a number of seats equal to that of the women there employed. This law differs from that which will come into force in Germany on April 1st, as the latter provides only for a sufficient number of seats. The English law of 1899 provides one seat for each three women employed.

Prevention of Malaria in Italy.—It is stated that in the budget of the Italian minister of the interior there will be included a sum of money for the prosecution of the campaign against malaria, which has already been begun in various parts of Italy under the influence of the experiments of Professors Celli and Grassi. This money will be devoted by the government to the carrying out of new experiments and the establishment of prizes. The Italian parliament has before it a bill for the prevention of malaria, by which it would be made compulsory on all employers of labor in malarial districts to make provision for the lodging of laborers with proper precautions against infection in accordance with the present state of knowledge.

Vital Statistics of London for 1899.—According to Mr. Shirley Murphy's report, the population of London is estimated at 4,568,689 and the recorded death rate per 1,000 was 19.3 for the past twelve months. This death rate corrected for age and sex distribution amounts to 21.1, which is the highest since 1895. The metropolis, however, still justifies its reputation as one of the most healthy large towns, when its death rate is compared with those of other English towns having populations which exceeded 200,000 persons at the census of 1891, for out of twelve such towns London had a lower death rate than any except Bristol, Bradford, Hull, and West Ham. The death rate from cancer during 1899 maintained the progressive increase which has been in evidence now for many years.

To Close the Front Door of Street Cars.—The MEDICAL RECORD has long strenuously urged that the front doors of street cars be kept shut. With its customary apathy, however, the New York public have endured the discomfort and incurred the danger to health involved in the custom without protest. Latterly the community has come to a sense of its foolishness in permitting the conductor to be the master of the situation, and it is now announced that the railroad commissioner of the assembly on Wednesday, February 13th, gave a hearing to Mr. Ritchie's bill to compel companies operating surface or elevated railroads in Greater New York to keep the forward or front door of each and every car in actual operation upon such railroads, closed and secured against the ingress or egress of passengers for a period of six months, from October 15th until April 15th. Mr. Ritchie has been fairly deluged with petitions in favor of the bill. Even the worm will turn.

Annual Report of Cooper Union Institution.—The annual report for 1900 of the receipts and expenditures of the Cooper Union shows that the total revenue was $104,282.86 and the expenditure $97,717.49, of which latter sum $22,639 was spent in reconstruction and new laboratories.

$100,000 for Tuberculosis Hospital.—On February 7th Senator Davis, of Buffalo, introduced in the Senate a bill appropriating $100,000 for the construction of buildings for the New York State hospital for the treatment of incipient pulmonary tuberculosis. The plans are to be prepared by the State architect. The buildings are to be large enough to accommodate at least one hundred patients besides officers, employees, and attendants. The additional sum of $20,000 is appropriated for the equipment and furnishing of the hospital. This amount will be available on January 1, 1902.

Mount Sinai Hospital.—The statistics of Mount Sinai Hospital, as presented in the annual report, show that the number of patients treated during the year was 3,352. Of this number 1,963 were discharged cured. Accident cases treated not included in the above were 592. More than four-fifths of the patients were treated gratuitously. In the dispensary there were 86,431 consultations and 77,663 prescriptions were filled. With regard to the new hospital building to be constructed at 101st Street and Madison Avenue, it was reported that of the $1,650,000 required all but $225,000 had been subscribed.

Anti-Cigarette Bill for Utah.—Representative John L. Belch, of San Pete County, has introduced in the Utah legislature a sweeping anti-cigarette bill providing for a fine of not less than $10 or more than $200 to be imposed on any person, firm, or corporation that sells, gives away, or otherwise disposes of cigarettes or cigarette paper to any person, no matter what his age may be. The bill also provides for the arrest and fining of persons smoking cigarettes.

Charity in 1900.—The amount given away for philanthropic purposes during the year just ended, says *Charities*, is reported to have reached $60,000,000. Almost exactly half of these donations have been made to educational institutions. Libraries have re-

ceived about $6,500,000, mostly for new buildings. Charities have received $13,400,000, an increase over the previous year; churches and church enterprises $8,800,000. Though this is a splendid record, it falls short of the donations and bequests of the previous year by $20,000,000.

Tuberculous Cases to be Quarantined. — The United States commissioner of immigration has decided that tuberculosis is a disease which may subject the patient to quarantine.

Decoration for Dr. von Holleben.—Emperor William has bestowed upon Dr. von Holleben, the German ambassador at Washington, the Crown Order of the First Class.

Took Poison for Headache.—Frank Fisher, a member of one of the most prominent families in Maryland, died at his residence in Baltimore on February 7th, from poison taken in mistake for a headache remedy.

Dr. Francis J. Quinlan.—A complimentary dinner and loving-cup were given to Dr. Francis J. Quinlan on Wednesday evening, February 8th, on his accession to the chair of laryngology at the New York Polyclinic, by the members of the Celtic Medical Society.

Bubonic Plague at Cape Town.—The appearance of bubonic plague at Cape Town seems likely to add to the difficulties of the situation in South Africa. The authorities there have decided upon a wholesale extermination of rats. Should the disease spread it will necessitate changes in the military arrangements.

Ophthalmological Section, New York Academy of Medicine.—At the annual election of the ophthalmological section of the New York Academy of Medicine, held on Monday evening, January 22d, the following officers were elected for the ensuing year: *Chairman*, Dr. John E. Weeks; *Secretary*, Dr. Henry H. Tyson.

Bill Against Christian Scientists.—A bill has been introduced in the Massachusetts legislature, which is aimed at faith curists, clairvoyants, and persons practising magnetic healing. The bill aims to have inserted in the present medical law (chapter 458 of 1894) a new section providing that "whoever, not being registered, shall advertise or hold himself out to the public as a healer of disease, or able to abolish disease or the symptoms of disease, or as competent to do surgery, or shall in any way treat or prescribe for the sick or injured for gain, shall be punished by a fine of not less than $100 or more than $500 for each offence, or by imprisonment in jail for three months, or both."

Congress on Tuberculosis.—The London *Practitioner* says: "The arrangements for the congress on tuberculosis, which is to open in London on July 22, 1901, are making steady progress. Among the subjects to be discussed in the section of medicine are the influence of climate on consumption and the extent to which cases can be grouped for treatment in certain climates, and the question of sanatoria. In the pathological section the following subjects are proposed for discussion: 1. The varieties of tuberculosis (morbid anatomy and histology). 2. The morphological and physiological variations of the bacillus tuberculosis and its relations: (*a*) to the other acid-fast bacilli; (*b*) to the ray fungus and other streptothrices. 3. The tissue changes and constitutional effects produced by the various constituents of tuberculosis. 4. The pathology of tuberculous conditions requiring surgical interference. 5. Mixed infections in tuberculosis. 6. The congenital factor in tuberculosis. There is every prospect of a meeting that will lead to useful practical results."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ended February 9, 1901. Passed Assistant Surgeon J. A. Guthrie detached from the *Franklin* and ordered to the *New York*, February 18th. Surgeon A. M. D. McCormick detached from the naval hospital, Norfolk, Va., and ordered to the Naval Academy, February 2d. Passed Assistant Surgeon R. Spear detached from the *Buffalo* on arrival at Cavite, and ordered to the *Isla de Luzon*. Assistant Surgeon W. B. Grove detached from the *Vermont* and ordered to the naval hospital, New York. Assistant Surgeon W. H. Bucher detached from the naval hospital, New York, and ordered to naval hospital, Norfolk, Va. Assistant Surgeon M. V. Stone detached from the *Isla de Luzon* and ordered to the *Buffalo*. Medical Inspector E. Z. Derr ordered to the Naval Academy, February 14th. Surgeon W. R. DuBose detached from the Naval Academy, February 13th, and ordered to the *Wisconsin*. Medical Inspector D. M. Bertolette ordered to the *New York*, February 16th.

Camps for Tuberculosis in Pennsylvania.—The forestry commissioner of the State of Pennsylvania, Dr. J. I. Rothrock, has devised a plan for the open-air treatment of pulmonary tuberculosis in impecunious patients. He proposes the establishment of camps on the various forest reservations of the State that may be suitably located for the purpose, where individuals suffering from pulmonary tuberculosis, but without means to seek climates better suited to their condition, may spend several months in the summer. The first camp is to be opened on a reservation in Clinton County, situated two thousand feet above the level of the sea. This reservation has an area of forty-five thousand acres and is contiguous to two other large reservations. The plan contemplates the erection of large tents, with permanent foundations and anchorages, so that they will withstand the effects of the most violent storms. The tents will be provided with heavy wooden floors and be placed fifteen feet apart. In front of each tent a covered wooden platform raised from the ground will be erected, so that the invalids may not on rainy days be prevented from taking their customary exercise. The intention is to permit those who care to avail themselves of the privilege to live as fully as possible out of doors.

The State will not be asked to contribute any money to the support of the enterprise, as sufficient has already been subscribed for the purpose from private sources. The patients will be furnished only shelter free of charge, but they will have to provide their own means of living. They will be required to adhere rigidly to the fish and game laws and all laws for the preservation of forests, including precautions in the use of fire. If the plan proves successful a second camp will be established on a forest reservation in Dauphin County, overlooking the Lykens Valley at an elevation of about fourteen hundred feet; and eventually similar camps would be established on every healthy forest reservation in the State.

Opposition to the Proposed Changes in the Lunacy Law.—The board of managers of the State Charities Aid Association, at a meeting held on February 8th, passed resolutions against senate bill No. 255 and assembly bill No. 396. These bills propose to repeal the existing provision of law which requires that the president of the State commission in lunacy must be a physician who has had five years' actual experience in the care and treatment of the insane and who has had experience in the management of institutions for the insane. The board of managers opposes the bills because the extensive powers possessed by the State commissioner in lunacy require the knowledge of the construction and equipment of buildings especially designed for the treatment and custody of the insane, experience of the requisite number and qualifications of physicians, nurses, and employees in State hospitals for the insane and of their proper salaries, a knowledge of the quantity and quality of food supplies to be allowed, and because the State commission in lunacy is practically a court of appeals, to which an appeal may be taken in behalf of any person who is forcibly detained in a private or public institution for the insane and who it is claimed is not insane.

Obituary Notes.—Dr. Charles A. Cowgill died at Philadelphia on February 2d, at the age of seventy-five years. He was born at Dover, Del., was graduated from the Pennsylvania Medical College in 1846, became a surgeon in the Union army during the War of the Rebellion, and served with distinction in many Southern hospitals. At the close of the war he went to Florida, and in 1876 he was appointed by the governor controller of the currency, a position that he held until 1880.

Dr. Henry S. Mellinger died at Creswell, Pa., on February 6th, at the age of seventy-nine years. He was graduated from Jefferson Medical College in 1845.

Dr. F. M. Bennett, a graduate of the Medical College of Virginia in 1878, died in Montgomery, W. Va. He was a member of the Medical Society of Virginia, member of the State board of health of West Virginia, president of the Fayette County (W.Va.) board of health, and medical examiner for the New York Life Insurance and other companies. He was an enthusiastic advocate of life insurance for medical men, and left an estate of nearly $12,000, which consisted almost entirely of insurance.

Progress of Medical Science.

New York Medical Journal, February 9, 1901.

Some Remarks on Epidural Hemorrhage without Fracture of the Skull and Report of a Case.—By J. S. Horsley. The patient, a man aged twenty-one years, was struck with a club. He was momentarily stunned, but soon picked himself up and felt all right. In an hour and a half he became stupid but could be roused. In twenty-four hours his condition seemed to call for operation. There was a small contusion on the left parietal eminence. The patient was in profound coma. His pupils were slightly contracted, were equal, and would not respond to light; his breathing was slow and stertorous but not very deep; the pulse was irregular and intermittent, and on the operating-table, before the clot was reached, would vary from 110 to 160; the temperature was 97° F. The right side of his body and face was paralyzed, and the left arm and leg were in constant jerking convulsions. He had lost control of the bladder and rectum. The left parietal eminence was trephined and a large blood clot found. There was no fracture of the skull, not even a fissure. The trephine opening was enlarged with rongeur forceps, and a quantity of blood, estimated as from four to six fluidounces, was removed by means of the finger, a uterine curette, and small gauze mops on artery forceps. The opening was a little above the middle of the clot, which measured an inch and a half deep at its centre and covered an area about four inches in diameter. Only slight bleeding occurred after the clots were broken up and removed; so the space was loosely filled with iodoform gauze and a rubber drainage tube inserted. A few silkworm-gut sutures were introduced and left untied. Recovery was uneventful, the patient being discharged about a month after operation.

A Case of Gastro-Intestinal Hemorrhage Caused by Fatty Degeneration of the Right Ventricle of the Heart.—By Charles Phelps. The patient was a man aged fifty-eight years, a free liver, who had accumulated much abdominal adipose tissue and had a small umbilical hernia which was operated on. Four days after operation he went into collapse, and during the last day of life had several hemorrhages from the bowel, succeeded by hemorrhage from the stomach, proving fatal. Autopsy showed in the liver the following changes: (1) Moderately extensive fatty infiltration. (2) A less decided cortical atrophy due to chronic passive congestion. (3) Marked obliterative arteriosclerosis (endoarteritis) of the small branches of the hepatic artery. (4) A moderate degree of chronic interstitial hepatitis. The lungs were small and nearly bloodless, but otherwise of normal appearance. The heart was of normal size. Its right ventricle was covered with a layer of fat at least three-fourths of an inch in thickness, and the wall of this ventricle was of no greater thickness than paper and almost pultaceous in character. The left side of the heart was less encumbered by fatty deposit, and had suffered less fatty degeneration of its fibre. The left ventricle was firmly contracted and empty of blood; the right ventricle contained blood in small amount. The extent to which the cirrhotic disease in the liver had advanced was obviously insufficient to account for the fatal gastro-intestinal hemorrhage; but the condition of the heart seems to afford adequate explanation.

Auto-Intoxication from Renal Insufficiency with and without Diseased Kidneys, with Reports of Some Remarkable Cases.—By J. T. Jelks. The author believes that uræmia may occur in persons with perfectly sound kidneys which are imperfectly eliminating products of body waste. If urea or a kindred product becomes stored in the body, one of several things may occur: a general condition of uricacidæmia, manifesting itself in vertigo, contracted capillaries, arteriosclerosis, cold skin, especially of the extremities, so-called sick headache, which is now recognized as uric-acid headache; "the blues" or melancholia, palpitation of the heart, interrupted heart beat, various forms of skin diseases, rheumatism, gout, endocarditis, pericarditis, myocarditis, hysteria, epilepsy, and genuine insanity. Various clinical histories illustrate the foregoing statements. He closes by saying that those patients who are suffering from renal insufficiency because of nephritis usually die, not from the nephritis, but from the cardiac complications, namely, the hypertrophy and subsequent dilatation, with which, sooner or later, all these cases are afflicted. Hence the main indications for treatment are connected with the heart. If it is pounding because of capillary contraction or arteriosclerosis, nitroglycerin, opium, chloral hydrate, or iodide of sodium should be given to overcome the peripheral resistance. Careful watch should be kept on the heart, and if dilatation is threatened, digitalis infusion or digitalin should be prescribed, with rest in bed.

A Clinical Analysis of Digitalis and its Preparations, Calling Special Attention to the Glucosides and More Especially to Digitoxin.—By L. L. Solomon. The author makes a plea for a more careful study of the various principles of this drug which he enumerates and the action of which he compares. He says that when we order this remedy we should have very definite conceptions as to just what effect we desire, whether an immediate or a slow result, a cardiac action, a diuretic action, or a combination of the latter two. On this decision should depend the choice of a particular preparation. Concerning digitoxin he says that as a diuretic it is superior to digitalin, since it actually dilates the renal vessels while stimulating the heart. Furthermore, its action is prompter and more certain than that of digitalin. It manifests its effects oftentimes within twelve hours, and is less liable to cumulative action than digitalin. Because of the uniformity of its action and of its energy and strength, no doubt digitoxin has the brightest future of all its sister glucosides. A series of fourteen cases illustrates the therapeutic points made in the paper. A solution of digitoxin is liable to precipitate on coming in contact with the secretions of the body. The following solution has, after experimentation, been found to be stable and will not precipitate upon contact with blood serum, water, or sodium-chloride solution: ℞ Digitoxin, gr. $\frac{1}{50}$; chloroform, ♏ iss.; alcohol at ninety per cent., ♏ xxiii.; water sufficient to make ℥ ss. M.

The Closing of Cutaneous Wounds without Suture.—Howard Lilienthal commends the use of sutures for the deeper layers of tissue, but in his operations of recent years the wound in the skin has been left covered merely with sterilized gutta-percha tissue until healing was well under way, when the edges have been approximated with strips of india-rubber zinc plaster twenty per cent. Still more recently he has applied these plasters at the time of operation, and has had good results. He finds the trade preparation called sterilized Z.O. strips useful for the purpose indicated. Before applying the plaster one must be careful to check all hemorrhage and to dry the skin thoroughly with alcohol or ether. The strips are then laid on while an assistant adjusts the edges of the wound. The method should not be used when there is tension, but only when the wound can be closed without force. It is perfectly applicable to the partial closure of wounds when drainage is employed. The strips should be removed on the fifth or sixth day by loosening both ends and drawing them toward the wound.

Tracheal Injections in the Treatment of Pulmonary Tuberculosis.—By T. Morris Murray. The author has used injections in thirteen cases. Cough and expectoration were lessened, temperature was lowered, and the general condition of the patient improved. He prefers Mundell's solution of the essences of thyme, eucalyptus, and cinnamon, of each 5 gm. in sterilized olive oil, 100 c.c. Each injection should consist of 3 c.c.

Amœbic Abscesses of the Liver, with a Report of Four Cases.—By C. R. Darnall.

Intestinal Obstruction.—By L. A. Hering.

Philadelphia Medical Journal, February 9, 1901.

A Case of Cocaine Habit of Ten Months' Duration Treated by Complete and Immediate Withdrawal of the Drug.—George William Norris tabulates the following facts: (1) Cocainism is the most insidious of all drug habits. The use of the drug being unaccompanied by disagreeable after-affects—headache, nausea, vomiting, etc., which are met with after the ingestion of opium or alcohol—the vice is readily and rapidly established. (2) Cocainism is occasionally acquired by the local use of the drug in diseases of the nose and throat, teeth, etc., but more often as a substitute for opium or alcohol. (3) Cocaine is eventually tolerated by the system in huge doses. (One case is recorded in which gr. lx. were daily consumed.) (4) A relatively large number of habitués are found in the medical and dental professions. (It is said thirty per cent.) (5) The continued indulgence in cocaine invariably, and usually soon, leads to marasmus, with mental, moral, and nervous degeneration. (6) The smallest fatal dose on record is gr. ⅓ hypodermically. (7) While many cases of acute intoxication are being continually reported, there are relatively few fatal cases. The majority of such are the result of large doses injected into the urethra and bladder. (8) The amount of cocaine sold yearly is rapidly increasing, and its self-prescribed use among the laity and lower classes is becoming proportionately more frequent.

Exophthalmic Goitre of Syphilitic Origin.—R. Abrahams, after reviewing several cases, makes the following comments: (1) The occurrence of exophthalmic goitre in three undoubted syphilitics cannot be regarded as either an accident or coincident. (2) The old dictum which relegates the origin of exophthalmic goitre to a perturbance or disturbance in the cervical sympathetic system should receive attention only after the existence of syphilis, present or past, is absolutely excluded. (3) Those cases which yield to mercury or iodides should be favorably looked upon as being of syphilitic origin. (4) Cases in which all the orthodox remedies fail should be put to the test of specific treatment. (5) Cases which are characterized by gangrene of the extremities, various pigmentations of the skin, nocturnal headaches, or other suspicious luetic symptoms, should receive the benefit of specific remedies.

Case of Blindness from Sympathetic Ophthalmitis, Complicated with Secondary Glaucoma, Restoration of Vision by Two Iridectomies, One with Extraction of Lens, an Iridectomy, and Tyrrell's Operation of Drilling.—By Charles A. Oliver.

Remarks upon the Construction of Amputation Stumps, with a Report of Two Cases of Amputation by the Osteoplastic Method of Bier.—Alexis V. Moschcowitz states that every amputation stump must (1) be able to support the weight of the body; (2) be painless; (3) be no more liable to local disease than any other portion of the body; (4) disfigure its owner as little as is commensurate with the nature of the ailment. The technique of amputation of the leg is taken as a prototype: (1) A large anterior flap, with its corners rounded, is formed, its base occupying somewhat more than half of the circumference of the leg. (2) The next step is the formation of the osteoplastic flap. (3) Ablation of the leg; the method of doing it depending upon the length of the anterior flap. (4) Ligation of the bleeding vessels. (5) The osteoplastic flap is turned over the divided surfaces of the bones, and its periosteal fringe is sutured to the periosteum of the tibia and fibula, or to fasciæ and tendons in its proximity. (6) Suturing of the skin. The author believes that Bier's method of amputation is the operation *par excellence* in all cases, with the exception, perhaps, of diabetic and senile gangrene.

Parasites in the Blood.—Leon T. Le Wald writes that of the true parasites which are found in the general systemic circulation, there are two of great importance: (1) The filaria sanguinis hominis, causing the disease known as filariasis. There are three varieties of this parasite, viz., filaria nocturna, filaria diurna, and filaria perstans, the terms indicating their special characteristics. The transmission of this parasite by means of the mosquito has been established. (2) The plasmodium malariæ (tertian, quartan, and æstivo-autumnal). The parasite, after developing in the stomach of the mosquito, breaks up into small bodies which pass to the salivary glands and thus into the proboscis of the mosquito. The mosquito thus acts not only as the definite host of the malarial parasite, but also as the transmitting agent.

General Remarks on the Combination of Ether (Fifty-seven Parts) and Chloroform (Forty-three Parts), Known as the M. S. Mixture.—Edward Adams sums up the advantages of the M. S. Mixture as follows: (1) The stage of excitement and struggling are not marked. (2) It requires a short time to get a patient under—five or ten minutes. (3) Very little of the anæsthetic is required. On an average about 40 c.c. an hour are used. (4) It is a comparatively safe anæsthetic. (5) It is very pleasant to take. (6) The after-effects marked are not. (7) Patients recover quickly. (8) It can be used in nearly every condition in which either chloroform or ether is employed.

A Report of Some Cases of Abdominnal Surgery with Remarks on the Diagnosis of Carcinoma of the Cæcum and the Surgical Treatment of Carcinoma of the Liver and the Gall Bladder.—By Charles Greene Cumston.

Some Unusual Cases of Infectious Diseases: a Clinical Report.—By Delancey Rochester.

Journal of the American Medical Ass'n, Feb. 9, 1901.

Movable Kidney, from the Standpoint of the General Practitioner.—Alex. Marcy says that the treatment of this

condition may be divided into medical, mechanical, and surgical: (1) The medical treatment would consist in the use of such measures as would improve the general health of the patient, together with the accumulation of surplus fat. (2) The mechanical treatment consists in the use of elastic bandages, sometimes fitted with a special pad, called a kidney pad, and in some cases this device relieves the symptoms, but probably never keeps the kidney in its proper place. (3) The ideal treatment is surgical, and with the present methods is attended by practically no mortality when it is not complicated by other abnormal conditions. The author strongly urges that every patient weighing less than one hundred and twenty pounds who complains of general nervous symptoms, indigestion, palpitation, etc., be carefully examined for movable kidney. If this condition is not revealed by the first examination, the search should not be discontinued till after several trials have been made.

Preventive Treatment of Migraine.—E. W. Mitchell in discussing this subject speaks of the correction of ocular defects, uterine and menstrual disorders, removal of adenoid growths, and the correction of vicious habits and hygienic sins. The writer believes that the essential in preventive treatment is the withdrawal of the red meats from the diet. The outline of treatment is as follows: (1) Red meats are to be rigidly excluded. Water may be taken very freely. Meals should be regular and moderate. (2) The medicinal treatment aims to regulate the bowels, to promote intestinal antisepsis, and to stimulate the liver. The same end may be attained by various means. The various salicylates are useful. An occasional mercurial is required. (3) As much outdoor exercise is to be taken as possible. Hot baths two or three times a week are indicated, and in some cases the morning cold sponge bath.

Treatment of Menorrhagia of Pelvic Origin by Electricity.—G. Betton Massey believes that electricity offers a most valuable remedy for the permanent cure of persistent menorrhagia even of the most severe forms. The method may be carried out in office practice, is free from risk to already congested appendages, and may be relied on to cure when conjoined with intelligent regulation of the general health and habits of the patient.

Ovulation and Menstruation Not Interdependent Functions.—C. C. Thayer speaks of ovulation without menstruation, menstruation without ovulation, and conception without menstruation. He concludes that menstruation is not an integral part of ovulation, nor an absolute factor of conception, though usually concurrent and attendant.

Boston Medical and Surgical Journal, February 7, 1901.

Gonorrhœal Infection.—Benjamin Tenney thinks that specialists have greatly overestimated the number of persons suffering from this disease. His present impression is that twenty per cent. of the males and five per cent. of the females of the community may have become infected, but certainly not more. He has never had a gonorrhœal patient who was a total abstainer, and rarely one who did not admit an excess of alcohol at the time of his infection. This, of course, can be reasoned out in two ways, but the author cannot help believing that alcohol in the circulation or in the urine affects the urethral epithelium and partially destroys the normal resisting-power of the cells. Abbott's experiments on rabbits prove that alcoholized animals show the effects of inoculation with bacteria earlier than the non-alcoholized, and in the case of the streptococcus inoculation the lesions produced are more pronounced. We know clinically that a declining gonorrhœa takes a fresh start if the patient neglect the advice to "let rum alone."

Treatment of Acute Gonorrhœa.—Franklin G. Balch says that for the abortive treatment he has come to believe in only three remedies used as injections: nitrate of silver, permanganate of potassium, and protargol. The last-named is a safe injection for the patient to use himself. A one-half-per-cent. solution is strong enough to begin with, and if there is much scalding this should be diluted. An ordinary two-drachm syringe should be used, and the injection retained for at least three minutes. This should be repeated three times a day for the first ten days, and then at longer intervals until a cure is effected. If the patient presents himself only after the disease has been fully developed for several days, there is no use trying to abort the trouble. It is usually safest to give no local treatment, but to rely on medicines. As the gonococcus grows in an alkaline medium, drugs to render the urine alkaline would seem to be contraindicated. Two quarts of water a day should be drunk. Compound salol capsules are good, taken after meals and before going to bed. A simple diet is best, without alcohol, or peppery foods or drinks.

The Bacterial Diagnosis of the Gonococcus.—Oscar Richardson gives minute directions for the detection of the gonococcus. The necessity of rigidly subjecting the suspected gonocci, obtained in cultures, to certain criteria described, is emphasized by a recent observation of a case of acute arthritis of the knee, clinically of gonorrhœal origin. Cover-glass examination of the exudate showed Gram decolorizing cocci inside of the pus cells, which were regarded at the time as gonococci. At the time the pathologist had no doubt that the case was one of gonorrhœal arthritis. The cultures, however, from the exudate in the knee showed an organism which had a considerable resemblance to the gonococcus, so much so that, only after it had been cultivated through a number of generations and had been carefully subjected to various tests, it was declared not to be the gonococcus.

Gonorrhœal Prostatitis.—John Babst Blake has not been able to obtain accurate statistics of the frequency of this affection, but thinks that seventy per cent., as given by Montagnon and Eraud, is not excessive. A well-defined abscess, however, is infrequent. The beginning of congestive prostatitis may be suspected when the symptoms of an existing posterior gonorrhœa increase, and pain and a feeling of soreness and weight deep in the perineum become especially prominent. The patient should be put to bed, the bowels moved by salines, the diet made bland, and hot rectal injections of moderate size given and retained. Opium may be given in suppositories and oleum santali will modify the accompanying cystitis. European writers recommend Finger's hollow bulbous rectal tube, through which flows a continuous stream of cold water.

When is a Gonorrhœa Cured?—Paul Thorndike puts the question and says that it cannot be answered. Before it is safe to marry, all acute cases should be freed from all traces of discharge, both that visible at the meatus and that showing as shreds in the urine, and should remain thus free for a period of months. In the chronic cases the cause of the discharge, whether it be a stricture already formed, granulating patches, areas untreated and uncured in the posterior urethra, involvement of the seminal vesicles, etc., must be sought for and treated and cured. This can usually be done, but often takes a number of months for its accomplishment. Having been so accomplished, the patient must pass through a period of probation similar to the one mentioned above.

Gonorrhœa in Women.—W. L. Burrage says that the majority of authors give the following as the most frequent seats of chronic gonorrhœa in the order of frequency: urethra, cervical canal, Bartholini's glands, uterus, tubes, vulva, vagina, and bladder and rectum. Clinically, acute gonorrhœa in the female is much less frequent than in the male. The disease is not always preceded by a period of acute invasion, and for this reason gonorrhœa in women is often overlooked. It is difficult to say when a woman is entirely free from the danger of transmitting gonorrhœa, but we may consider that she is cured when there are no signs of chronic inflammation about the uterine organs, and when two or more negative cultures have been taken from the urethra and cervical canal.

Treatment of Chronic Gonorrhœa.—Gardner W. Allen says that the objects to be aimed at are the removal of fibrous deposits, the restoration of the rigid and thickened mucous membrane to approximately its original soft and elastic condition, and the cleaning out of diseased follicles and glands. The first principle of this treatment is dilatation of the anterior urethra by means of the four-branched dilators of Kollmann. After dilatation the local application of various remedies is effected by means of injections or irrigations, and later the urethra is inspected through the endoscope and local applications are made under control of the eye to such points as require them. The author describes the course of procedure in detail.

Gonorrhœal Conjunctivitis.—Charles H. Williams in ophthalmia neonatorum irrigates the eye with a warm saturated solution of boric acid, used in quantities of half a pint to a pint at a time by means of a small fountain syringe and a tube provided with a glass nozzle with its end drawn out to a tube not over one-eighth of an inch in di-

ameter, the end carefully rounded in the flame. This should be cautiously inserted between the eyelids with the end carefully turned away from the cornea toward the upper part of the conjunctival sac and moved across the lid so that the discharge may be removed from the whole of the conjunctival sac by the warm stream of irrigating fluid. The author gives further directions as to treatment.

The Seminal Vesicles in Gonorrhœa.—Charles L. Scudder considers that acute seminal vesiculitis is extremely rare. At the outset, measures directed toward checking the inflammatory process should be taken. If pus is present it should be evacuated by incision and drainage through the rectum or the perineum. Chronic seminal vesiculitis causes not inflammatory but functional or neurotic symptoms. The treatment by massage of the vesicles should be instituted before extirpation is resorted to. The author describes the inguinal, perineal, and sacral operations.

The Lancet, February 2, 1901.

The Hemorrhagic Diathesis in Typhoid Fever and its Relationship to Purpuric Conditions in General.—By A. G. Nichols and G. E. Learmouth. The term "hemorrhagic" in this connection should be restricted to those cases in which multiple hemorrhages take place, and which are evidenced clinically by purpuric eruptions into the skin, oozing of blood from the mucous membranes, epistaxis, hæmoptysis, hæmatemesis, melæna, or metrorrhagia. The authors have made a careful bacteriological and histological examination of the various tissues in this class of cases. In regard to classification they think that in the light of our present knowledge it would be better to speak (1) of an "essential" purpura hæmorrhagica, including under this term morbus maculosus, morbus Werlhofii, purpura simplex, peliosis rheumatica, and purpura urticans. Whether scurvy (purpura scorbutica) should be included in this class is perhaps doubtful, since "essential" purpura is a sporadic disease, while scurvy is apt to be epidemic and endemic. Some observers, however, would place scurvy with the others in the "infective" category. Babes particularly has described a bacillus which he thinks is the cause, but other observers have obtained negative results. Hæmophilia certainly should not be included in the first group, since it is characterized by family and hereditary peculiarities. It might be termed a "normal" condition for certain individuals and is not to be regarded as a true pathological state, since it is a permanent and not an incidental or transient condition. The second group might be termed (2) "symptomatic purpura" and would include all those cases which are met with in the course of the infective fevers, such as typhoid fever, variola, measles, scarlet fever, pest, yellow fever, sepsis, acute yellow atrophy, icterus gravis, etc. A third group might be termed (3) "cachectic," including forms found in pernicious anæmia, leukæmia, carcinoma, Bright's disease, etc. A fourth group is (4) the toxic purpuras, such as are met with in certain forms of poisoning (snake-bite, phosphorus, copaiba, antipyrin, etc.). A fifth form is that found in (5) disseminated sarcomatosis, to which attention has been called by Martin and Hamilton; here in one case which they studied there was actual sarcomatous invasion of the internal coat of the vessels and in another emboli of sarcoma cells were found. Whether these were the only factors or not seemed to be doubtful. The first two groups, and possibly the third, would fall under the head of "infectious" purpura.

Considerations Touching the Pathology and Relations of Diabetes.—First Baillie lecture by W. H. Dickinson. The author mentions among the relations between this disease and the nervous system the occurrence of phosphaturia, essentially the phosphate of lime. In severe and advanced conditions of diabetes the increase of urinary lime, practically all in the form of phosphates, may be termed extraordinary, since it is unexampled in any other disease. He has placed on record a case in which the daily excretion of lime exceeded 3 gm., another in which it exceeded 2 gm., and several in which it approached 1 gm. The average of the urinary lime in health, according to Dr. Parkes, is 0.26 gm. Call it 0.3 gm. by way of being liberal. The maximum of Dickinson's cases of diabetes was 3.38 gm., eleven times the average of health. The calcareous increase in these cases does not wholly depend on the amount of urine, for it is out of proportion to the diuresis. To take a single example—a woman passed in one day 4,980 c.c. of urine, which was found to contain 3.38 gm. of lime. Supposing that this urine contained only the normal percentage of lime, this would amount for the whole quantity of urine to under 1 gm. Thus the lime is increased out of proportion to the urine. Having regard to the affinity which exists between lime and sugar, it may reasonably be suspected that the superabundance of lime in diabetic urine may depend on the attraction of the sugar for the lime, as a consequence of which the sugar carries out the lime with it. But the facts give no encouragement to this supposition. He found that a patient with severe diabetes under strict diabetic diet passed on an average of two days 3.28 gm. of lime. When the urinary sugar was largely increased by the addition of sugar to the diet the lime amounted to 2.76 gm. With more sugar there was less lime—as if the one did not directly depend on the other. Much has yet to be learned concerning the connection of the nervous system with diabetes; but, having regard to the undoubted relation of the excessive secretion of the earthy phosphates with certain conditions of cerebral irritation, it cannot but be suggested as a provisional hypothesis that the extravagant exit of phosphate of lime in some cases of diabetes has to do with the state of the nervous system in this disease.

Selenium Compounds as Factors in the Recent Beer-Poisoning Epidemic.—F. W. Tunnicliffe and O. Rosenheim note the great discrepancy between the amount of arsenic taken and the severity of the symptoms produced thereby. They believe that some other substance thus far undetected has found its way into the beer along with the arsenic. In searching for such a substance their attention was directed to the possible impurities of sulphuric acid used in the handling of arsenical ores other than arsenic but exerting a physiological action similar to arsenic. Selenium and thallium at once suggested themselves. Their experiments have led them to believe that compounds of selenium have played a definite rôle in the recent beer-poisoning epidemic. This rôle, however, is subsidiary to that of arsenic. The presence of selenium in the beer would explain many anomalous cases, among which may be numbered those in which the dose of arsenic taken was very small, those in which arsenic could not be found in the excretion, and those also (notably two cases of infants at the breast) in which no arsenic could be found in the milk. In the absence of extensive pharmacological investigation upon the higher animals it is impossible to say to what extent the presence of selenium with the arsenic might modify the symptom complex produced by this latter poison. The most important conclusion, however, which they would draw from their investigations relates not to the past but to the future. In view of the poisonous action of selenium it is absolutely essential that all sulphuric acids used in the manufacture of food products should not only be arsenic but also selenium free.

Filatow's Spots in Morbilli.—By L. Falkener. These spots are now generally known (at least in this country) as Koplik's spots. Falkener has studied the records of seventy-six cases at a period in the disease when one could reasonably expect the spots to be present. From an examination of his figures it appears that whenever his cases were examined on the day of the first appearance of the definite onset of the exanthem (as apart from premonitory rashes) and the day preceding it these specific spots of Filatow were invariably present. It will also be noticed that the incidence for cases examined on either the second day of the exanthem or the second day preceding the exanthem was seventy-five per cent.; while for those on the third day of the exanthem or the third day preceding it the incidence was fifty per cent. Among his cases, whenever Filatow's spots have persisted up to the third day of the exanthem, they have nearly always by that time become very much diminished in numbers, and frequently in definition; while on the fourth and fifth days they were often barely distinguishable, and were in several cases far from typical in appearance. He has never seen them later than the fifth day. In most cases they disappeared earlier than the exanthem, but in one or two cases both spots and exanthem disappeared simultaneously. In every one of the seventy-six cases the spots were present.

An Intraperitoneal Method for Radical Cure of Inguinal Hernia.—By T. H. Wells. The different steps of the operation are enumerated in the following propositions: (1) Make an incision two and a half inches long in the linea semilunaris, ending over the external abdominal ring and passing through skin, fat, and superficial and deep fascia; (2) deepen the upper one and a half inches through the abdominal muscles, transversalis fascia, and subperitoneal fat, and having arrested all hemorrhage open the peritoneal cavity; (3) explore the sac with the finger and remove any gut; (4) insert forceps along the palmar surface of the finger, seize the apex of the sac and invert it, bringing it out into the upper wound; (5) stitch the sac, after giving it a couple of twists on itself to obliterate its cavity, to the peritoneum; (6) stitch up the external abdominal ring; and (7) close the wound by bringing the structures layer by layer into accurate apposition.

The Treatment of Typhoid Fever.—By F. J. Smith. The author presents a well-considered set of rules for the treatment of the disease, though nothing new is brought forward. He is disposed to be quite liberal in the matter of diet. The patient should never be awakened to be fed. As a means of relieving pyrexia he prefers tepid sponging to cold bathing. The condition of the abdomen should be

carefully watched and tested at every visit, and at the first appearance of tympanites all food should be stopped, though water should be continued. To relieve tympanites he advises the administration of two drachms of sodium sulphate every two hours until the bowels are moving freely.

Laparotomy and Cleansing of the Peritoneum in a Case of Tuberculous Peritonitis.—By G. W. Davis.

A Case of Primary Carcinoma of the Vermiform Appendix.—By T. R. C. Whipham.

Femoral Hernia.—Abstract of clinical lecture by W. H. Battle.

Reflections on Therapeutics.—By Harry Campbell.

British Medical Journal, February 2, 1901.

Remarks on a Case of Retroperitoneal Cyst.—John Ward Cousins gives the following history of a case: The patient was the mother of two children; her abdomen had been increasing in size for many months and she thought she was pregnant; she had suffered no pain nor was there any disturbance in health. The swelling of the abdomen extended from three inches above the umbilicus to the pubes. The long axis ran downward obliquely to the left, and a distinct sulcus was situated over the umbilicus. The walls of the abdomen were elastic and moved freely on the tumor, and its outline was clearly discernible. Fluctuation was very distinct in all directions. Resonance on percussion was well marked in the left flank and over both inguinal regions. Laparotomy was performed and the surfaces of the cyst when exposed were found to be continuous with the inferior layer of the mesocolon, the descending colon presented on the left, and the small intestines overlapped it below. The tumor extended backward toward the centre of the abdomen, and the vessels in every direction were much distended. Six pints of a clear fluid were removed by aspiration and the operation was completed by fixing the cyst to the lower angle of the wound and inserting a glass drainage tube. This was in 1897. Early last year the patient was seen again and was in good health.

Nervous Hyperpyrexia following Parturition.—Howard Distin emphasizes these interesting features in a case of this kind: (1) The force used to deliver the child—considerable traction being necessary—without the help of anæsthesia, and with little or no immediate shock to the patient. (2) The prolonged period which elapsed between labor and the advent of pyrexia, elevation of temperature being first noticed on the sixth day after labor. (3) The complete absence of any symptoms pointing to septicity, the lochia continuing normal and the abdomen free from tenderness throughout. (4) The long period (ten days) during which the fever continued, producing very little ill-effect on the general condition of the patient. (5) The occurrence of a rigor after each of the uterine douches, and at no other time. The erratic temperature was considered to be of purely nervous origin.

Strangulated Femoral Hernia: Successful Primary Resection of the Damaged Gut.—Henry Betham Robinson reports an interesting case, and from the technique employed he draws attention to the following points: (1) The accurate apposition of the mesenteric border of the cut ends was attained by the stitch similarly used by Maunsell in his method of resection. (2) The adoption of a continuous Lembert's suture whereby the sutured edges are more evenly supported and much time is saved. (3) The resection *in situ*, instead of making an abdominal incision, withdrawing the damaged gut, and running the risk of fouling the peritoneal cavity. Should any difficulty be met with in replacing the bowel, the opening can be enlarged and then resutured without causing any weakening in the lower part of the abdominal wall.

Carcinoma of the Liver at the Age of Twenty-four Years.—Daniel McKenzie reports this case, the remarkable feature of which is the youth of the patient when the illness commenced. The diagnosis of carcinoma as opposed to sarcoma was arrived at upon consideration of the chronic afebrile character of the illness and the bony, hard, and general enlargement of the liver.

Proof of the Presence of Sugar in Children.—P. Nobécourt states that in spite of the quantity of lactose ingested every day by the child in its milk, the condition of lactosuria cannot be determined in the normal state. Nevertheless, this condition is not rare in certain pathological states. In the normal condition of the child it is necessary to give large doses of lactose in order to cause its appearance in the urine. The infant organism is physiologically capable of caring for large quantities of glucose. Thus the appearance of an alimentary glycosuria has a certain value. In the gastro-enteritis of nurslings, E. Terrien has determined recently that glycosuria is observed in about half the cases with doses of glucose less than 4 gm. Unfortunately, this writer does not indicate whether the infections concerned are acute, temporary or prolonged, subacute or chronic. As to subcutaneous injections of glucose, G. Finizzio injected under the skin 2.50 gm. of glucose per kilogram of body weight and did not see any resulting glycosuria. The investigations should be carried on with great care, for it is not rare to see a temporary rise of temperature following these injections. In the actual state of our knowledge, the proof of alimentary lactosuria and saccharosuria does not appear to give important data relative to the functioning of the intestinal mucosa. On the contrary, the proof of alimentary glycosuria, whether the glucose be absorbed by the digestive tract or subcutaneously, has already furnished interesting results, and allows in a certain measure the appreciation of the functional activity of the liver and the tissues.—*La Presse Médicale*, January 12, 1901.

The Treatment of Acute Articular Rheumatism by Massage with Petroleum.—Hector Sarafidis concludes that massage with petroleum is the best treatment for acute articular rheumatism, for the following reasons: (1) The treatment demands very little expense, the oil being very cheap. (2) The treatment can be used as well in the country, far from a pharmacy, as in the city. (3) During the treatment, the patient is not surfeited with drugs, as the petroleum is sufficient to cure the rheumatism. (4) The treatment by petroleum can be used by everybody, for it can never cause any trouble. (5) Its application lowers the temperature. (6) Petroleum can be used on those suffering from Bright's disease. It is well known that in the course of an interstitial nephritis it is not possible to administer salicylate of sodium; the same observation must be applied to pregnant women.—*Revue de Thérapeutique*, February 1, 1901.

Annals of Surgery, February, 1901.

Gunshot Wounds in the Philippino-American War.—By E. F. Robinson. The paper is based on the records of 1,596 cases seen in the Philippines, supplemented by personal notes of 462 of the cases which came under the care of the author as operating surgeon. Two important factors militate against aseptic surgery in the tropics: the greater tendency to infection and the general poor health of the patient, whereby his reactionary powers are lowered. Conclusions are given in the following paragraphs: (1) The modern gunshot wound is generally aseptic, and should be treated on this supposition. (2) Asepsis is due chiefly to the character of the bullet, to the early application of first-aid dressing, and in a minor degree to the velocity of the projectile. (3) Primary hemorrhage from modern gunshot wounds is exceedingly rare, the blood-vessels being displaced rather than cut by the rapidly moving projectile. (4) The "explosive effect" of the modern bullet is much less common than recent military literature would indicate. This peculiar destructive effect is produced by the character of the tissue struck, as well as by the great velocity of the bullet. (5) Gunshot wounds of the chest are rarely infected. Simple antiseptic treatment, with aspiration of the pleura in cases of severe hemorrhage, is all that is necessary. (6) Gunshot wounds of the knee joint are usually aseptic, but if infected demand immediate amputation to save life. (7) Excision of the elbow is always a justifiable operation in severe shattering or infection of that joint. Resection of bones of other joints is rarely necessary, erasion or amputation being preferable. (8) Injuries of nerves from gunshot wounds can often be benefited by operative interference or resection. (9) In modern military surgery, abdominal section for gunshot wound is not justifiable; the patient's best chance of recovery lies in conservative treatment without operation.

Sarcoma of the Uterus.—By Van Buren Knott. The author has been able to collect notes of one hundred and eighteen cases from the literature of the last ten years. He reports a personal case of diffuse sarcomatous growth of the uterine wall occurring in a woman aged forty-three years. The mass consisted of several distinct spheroidal growths, and was intimately adherent anteriorly to the peritoneal investment of the bladder and posteriorly to the

broad ligament. It was shelled out without especial difficulty and with no hemorrhage, and the entire tumor or tumors removed *en masse* with the uterus, ovaries, and tubes. The case was recently operated on and cannot be considered cured, for a recurrence is greatly to be feared. The author regards the case as unique in pathology, combining as it does the features of a diffuse sarcoma of the muscular wall of the uterus with those of sarcoma of the cervix, although the bunch of small growths which closely resemble the grape-like cervical sarcomata were more solid than the latter, and did not contain the sticky gelatinous fluid common to them, making the resemblance one of conformation and appearance only.

The Improved Technique in the Operative Surgery of Carcinoma of the Stomach.—By W. G. MacDonald, M.D. The author especially commends in gastro-enterostomies von Hacker's method of attaching the jejunum to the posterior gastric wall with a re-anastomosis between the duodenum and the jejunum. During the past year he has operated eight times with seven recoveries. Anastomosis between the jejunum and stomach has generally been made by the suture method. For the secondary anastomosis he has uniformly used a Murphy button of moderate size. He claims the following advantages for the plan outlined: First, freedom from contamination of the wound by stomach contents; second, accessibility of the neighboring lymphatic nodes for extirpation; third, no subsequent danger from suture perforation; fourth, freedom from loss of blood; and, fifth, the great saving of time required for the operation. The surgeon is not embarrassed in the least by the amount of tissue which he removes, as no effort is made to bring the duodenum and the remainder of the stomach in apposition.

Cases of Compound or Complicated Fracture Illustrating the Value of Operative Interference in the Treatment of these Injuries.—By H. R. Wharton. The cases described comprise compound dislocation and fracture of the lower end of the tibia with fracture of the fibula, compound comminuted fracture of both these bones, fracture of the fibula with marked displacement of the lower fragment, fracture of the lower end of the fibula with fracture of the internal malleolus with marked and persistent deformity, comminuted fracture of the upper end of the humerus, excision of the shoulder joint with a useful arm, and extensive gunshot wound of the shoulder joint, excision of the joint with a useful arm.

The Journal of Tropical Medicine, Jan. 1 and 15, 1901.

Cerebro-Spinal Meningitis.—E. G. Hamilton Williams and Mary Hamilton Williams say that the epidemic of which they wrote in a previous article has not ended. Fresh cases are constantly arising, but many of them are of a mild type. The diplococci were found in over eighty cases, and in some they were found when the symptoms were slight, but a few days later became unmistakably severe. On examining the blood the first point noticed in nearly all cases was the marked polynuclear leucocytosis, and when this was found in a high degree the further investigation of other fields rarely failed to reveal the characteristic diplococci. It appears to the writers that this method of diagnosis, if confirmed by other observers, may lead to the recognition in the presence of an epidemic of many slight cases, which would otherwise be treated as "bilious attack," "febricula," etc., and arguing from the analogy of diphtheria, these slight cases may yet give rise in another patient to a severe attack. In addition, many obscure sporadic cases of the disease may be recognized, and the origin of outbreaks, which may have started from a very slight imported case, explained. Diplococci were found also in the sweat, the saliva, the nasal secretion, and the urine.

The Prevalence of Mosquitos and Malaria in Hong Kong.—J. C. Thomson has found two distinct species of Anopheles abundant in the colonies, and at least eight distinct species of Culex. The extirpation of malaria in the western part of the city must consist in the levelling and covering in of all the watercourses. The connection of malaria with disturbance of soil, an important point in Hong Kong, is by no means clear as yet. Grassi states that it depends on the creation during digging operations of puddles of water in which Anopheles breed, but this does not hold for Hong Kong, where the whole of the broken surface may show no single puddle, the sun drying the superficial layers as they are turned up, and yet where earth-cutting is invariably attended by an outbreak of fever. Culex is not known to act as a host to the malaria parasite, but it certainly does to the filaria, which causes the great group of elephantoid diseases. The author has found the larvæ of Culex in process of development in abundance in or about every house without an exception in which he has looked for them—in tea-pots, flower stands, fire buckets, hand basins, etc.

Report on a Glandular Ailment which Prevailed at Bacalar Chico, in February and March, 1900.—C. H. Eyles reports this epidemic, and says that the observation of Dr. Gann, the only medical officer who has actually seen any case in progress, bears out what has been gathered as to the nature of the cases, viz.: that after some febrile disturbance lasting for about three days, glandular enlargements, chiefly of the cervical glands, appeared. Unfortunately no material from any of the glands was forwarded for examination. The sudden appearance at the present time of a glandular ailment, with febrile phenomena, in any settlement, and attacking about twenty per cent. of the people, is strongly suggestive of plague. The disease might have been imported from Rio de Janeiro. If the disease was plague, it must have been of a mild type, and being introduced in a sparsely populated country, died out. No special mortality of rats, etc., was observed.

Striking Confirmation of Mosquito-Borne Malarial Infection in a Child Aged Three Weeks.—Dr. J. C. Graham, of Deli, Sumatra, reports that the child in question greatly alarmed its parents by suddenly developing a rise of temperature that could not be accounted for by any of the usual causes. In response to the question whether the child had suffered much from mosquito bites, the parents replied it was usually well looked after to prevent their occurrence, but that ten days previously the native servant had carelessly forgotten to close the mosquito curtains at night, with the result that the child was simply covered with mosquito bites the following morning. The irritation caused by these soon passed off, and the incident was forgotten. Acting on this information, the author examined the blood of the infant, and found the malarial parasite. The fever yielded readily to quinine inunction.

A Case of Hemiplegia; Operation; Recovery.—A. A. Bennett reports a case. The patient was trephined over the left Rolandic area. The brain bulged into the wound and there was no pulsation; the brain was explored with a needle in all directions and nothing found. The dura mater was freely incised and an induction current passed through the exposed convolutions. The patient was much collapsed after the operation, but a month later was practically well. He is now almost as intelligent as he ever was, which is not saying very much. The right arm and leg, which were the affected ones, are still weaker than the left, but apart from this they do not differ in any respect. The patient is eating very well, and has put on many pounds since the operation.

Typhus-Like, Erythematous, and Other Eruptions in Plague.—William Hossack says that in the past pandemics of plague, eruptions seem to have been not uncommon, and at times seemed to form one of the diagnostic symptoms. It is possible that the explanation of this may be found in typhus fever, particularly as in the present pandemic general eruptions have been of the rarest possible occurrence. Among those that have been noted are typhus-like, morbilliform, erythematous, urticarial, and sudaminous rashes. Partial local eruptions, though not so rare, have been uncommon—they include bullæ, pustules, petechiæ, and purpuric patches.

Case of Rhinorrhœa.—A. B. Dalgetty reports the case of a woman, a Hindu coolie, who suffered from a constant liquid discharge from the right nostril. The point of special interest consists in the fact that the fluid contained a multitude of ciliated organisms darting and turning and doubling about in all directions. The author describes the organism, which would seem to belong to the order Holotricha; genus Paramæcium; but to what species is doubtful. As to how the organism has gained a footing in the nose, there is nothing to show, nor does a rhinoscopic examination from the front discover from what part the discharge comes.

Case of Bronchocele in a Native of Perak, Malay States.—P. G. Edgar reports a case in a man born in Perak, where the disease is endemic. The swelling commenced in the patient's twentieth year, when it was the size of a marble, and it gradually enlarged to an enormous size. Both lobes of the thyroid are enlarged, and the enlargement appears to be cystic. The Malays attribute the origin of the disease to the water.

Il Policlinico, January, 1901.

A Study of the Intracellular Diplococcus of Weichselbaum and Jager, and of Epidemic Cerebro-Spinal Meningitis in Children.—A. Longo holds that the above-named diplococcus is the specific agent of epidemic cerebro-spinal menin-

gitis. This micro-organism is not one of a group, but is unique. The arguments hitherto brought forward do not in the least prove it to be a variety of the pneumococcus. The presence of the meningococcus is of less grave import than that of the pneumococcus in the cerebro-spinal meningitis of children. It is well to bear in mind that the meningococcus may be absent from the first liquid extracted by lumbar puncture, but appear in that of successive punctures. No prognostic importance is to be attached to the predominance of intra- or extracellular forms.

Injections of Gelatin.—F. Mariani gives the following conclusions as the result of his experimentation: (1) Hypodermic injections of gelatin in two-per-cent. solution are absorbed. (2) These hypodermic injections may increase the coagulability of the blood, or, within normal limits, modify its density, but physiological oscillations prevent any special results. (3) In the cases experimented upon by the author, hypodermic injections of gelatin, while they did not bring about a complete cure of aneurism, did certainly produce marked improvement. (4) These injections cause a rapid but transitory hæmostasis. (5) They are absolutely innocuous.

OUR LONDON LETTER.

(From our Special Correspondent.)

QUEEN VICTORIA'S LAST ILLNESS—ROYAL COMMISSION ON ARMY HOSPITALS' REPORT—CORONER'S JURY ON THE BEER POISONING — PLAGUE — ANOTHER V.C.—DEATHS OF DRS. SYMES, MYERS, SAUNDERS.

LONDON, January 25, 1901.

A WEEK of national anxiety and grief! That is what I have to chronicle. It is summed up in the simple phrases, the Queen is ill—the Queen is dead!

You must know all about it through the cable. Through it, too, we learn of your sympathy—your joint sorrow with us. This event casts all other news into the shade. Even telegrams from the seat of war have been pressed out of the prominent columns of our newspapers by that which touches every reader with a strange personal interest.

But this is not the place to enlarge on the event. Yet for medical readers a few items may be given respecting the last illness of the Queen. It was known in some circles, indeed it could not be concealed, that for months past the Queen's health was failing. Dyspeptic symptoms and insomnia had troubled her. Transient attacks of aphasia had been observed. They were very brief, without any motor paresis, but distinct enough for her physicians to recognize as important, especially as brain fatigue had been observed for some time previously. Some of these symptoms were recognized at Balmoral and continued at Windsor, where in November and December they were more marked. The journey to Osborne on December 18th was very trying to Her Majesty, but she rallied after two or three days and improved for a time in response to more rest. But feebleness increased with recurrent transient apathy and somnolence and aphasic indications. On January 16th (Wednesday) there were signs of cerebral exhaustion. On Thursday the symptoms were more marked, and slight flattening of the right side of the face was observed. From this time the aphasia and facial paresis, although incomplete, were permanent. On Friday the Queen was a little brighter, but on Saturday there was a relapse of the graver symptoms, which, with remissions, continued until the end. The heart beat regularly to the last. Within a few minutes of death the Queen recognized members of her family.

Among many fixtures postponed until after the funeral of the Queen is that of the adjourned debate at the Royal Medical and Chirurgical Society. When the society met on Tuesday, the president, Dr. Pavy, said the sad news made known but a few hours before rendered useful discussion impossible. The meeting at once adjourned and many others will also do so.

The report of the royal commission on the South African Hospitals is out. It extends over seventy-one closely printed folio pages containing an account of the more important evidence taken in Africa and here. This important and elaborate document is another flat contradiction for the allegations of Mr. Burdett-Coutts, whose charges may now be justly called slanders. But, as if determined to abide by them, he republished them only a few days before the issue of this report. "*Quem deus vult perdere*," etc. What is the value of Mr. Coutts' assertion beside the following deliberate conclusion of the royal commissioners:

"We desire to say that in our judgment, reviewing the campaign as a whole, it has not been one where it can properly be said that the medical and hospital arrangements have broken down.

"There has been nothing in the nature of a scandal with regard to the care of the sick and wounded; no general or widespread neglect of patients, or indifference to their suffering.

"And all witnesses of experience in other wars are practically unanimous in the view that, taking it all in all, in no campaign have the sick and wounded been so well looked after as they have been in this."

These conclusions of a commission, presided over by an eminent judge, will satisfy the public that Mr. Burdett-Coutts and the screaming plague of women must not be taken at their own valuation. Their charges have been shown to be baseless and reflect discredit on their intelligence and motives. I have all along said, let the Royal Army Medical Corps patiently await the decision of the commission. They have waited and have their reward.

On the subject of the supply of necessaries for the sick and wounded the commissioners find that all requisitions were promptly met. They do not even complain that the Royal Army Medical Corps was hampered by red tape, but they think that several records and documents might be shortened in many respects.

The hospital arrangements at Bloemfontein are dealt with at considerable length, and conclude that "the extent, suddenness, and virulence of the epidemic could not have been foreseen."

With regard to certain subjects the commission suggest that a committee of experts should be formed to inquire into them. These include the establishment and equipment of the Royal Army Medical Corps on a scale to fit it to cope with its work in times of peace and during smaller wars; provisions to enable surgeons and hospital equipments to be rapidly obtained in the event of a great war; the attraction to the Royal Army Medical Corps of a sufficient supply of officers of good professional attainments; the improvement of the ambulance and nursing service. Further, they think the committee should inquire as to whether the Royal Army Medical Corps should have exclusive control over necessaries for the sick and wounded so as to avoid delay due to requisitioning upon the Army Service Corps.

These are questions that have often been before the public, and it would be well to have them thoroughly investigated.

The coroner's jury in the beer-poisoning case have given a rather contradictory verdict—an open one, it is called—but they followed it up by censuring several of the persons and firms implicated. This was hardly to be expected from the advice of the coroner, for he exhorted them, when they said they could not agree, "to remember they were a jury, not individuals called upon to coerce each other; and if they could not agree who was to blame, to leave that in the hands of the police."

As to one of the firms censured, the coroner agreed with counsel that no evidence had been given justifying the blame. The chemist at the glucose works ceased to examine the sulphuric acid at the end of 1899, and his scientific superintendent either did not know this, or made no inquiry, and took no steps to see that the acid was pure, though he admitted he should have done so. Between the makers of acid, of glucose, the brewers, and the various chemists, it seems a case of divided responsibility unknown outside the War Office.

Suspicious cases of illness with four deaths among the crew of the steamship *Friary* while discharging cargo at Hull led to an inquiry. At first the cases were said to be influenza, then plague was suspected. Bacteriological examination by Dr. Klein shows that the latter was the disease. Early precautions had been taken and no more cases have occurred.

In the report of a cottage hospital the following somewhat strange statement occurs: "Notwithstanding the large amount of money expended for medicine and medical attendance there were but few deaths during the year."

Another medical officer, Lieutenant E. T. Inkson, has received the V.C. for carrying a wounded brother officer through a hail of bullets to a place of shelter.

Dr. J. G. Symes, who died on the 14th inst., aged seventy-five years, was for thirty-three years medical superintendent of the Dorset Asylum, where he abandoned mechanical restraints at an early period. He was a son of Admiral Symes.

You will have heard that Dr. Myers, who went to Brazil with the Liverpool expedition to investigate yellow fever, has fallen a victim to the disease. He had left Cambridge but recently to take up this work. He was in his twenty-ninth year.

Dr. Sedgwick Saunders, who has filled the important post of medical officer of health to the city since 1874, died on the 18th inst. He had in early days been in the Army Medical Service, but eventually settled in the city and long held an important position there. In 1870 he was the councillor who laid the foundation stone of the Guildhall Library and Museum.

"OPIUM TAKING IN ASIATIC COUNTRIES."

To the Editor of the Medical Record.

Sir: I have never lived in India, but I have resided a long time in China, and although your editorial in the issue of January 12th had special reference to India, its heading is my excuse for sending some literature and some of my views on the use of opium in China. The enclosed is, as you see, a copy of an editorial that appeared in the *North China Daily News* last May. This paper is the leading daily in China, if not in the East, and its utterances heretofore have always led the opium interests to regard it as "sound on the opium question." Under a separate cover I send a copy of "Opinions of Over One Hundred Physicians on the Use of Opium in China." A thousand copies of this pamphlet have been bought by Mr. B. G. Tsang, a Chinese gentleman now visiting in America, for free distribution. Any one desiring a copy can get it by sending four cents to me for postage, or by applying in person at No. 3 West Eighteenth Street, New York City. Mr. Tsang hopes that when the new treaties are made, China will be allowed to place opium on the list of poisons and have its sale restricted there just as it is in England and all other self-governing countries. If, according to Kipling, as reported by Dr. Dawbarn, opium is the "friend" and "mainstay of millions" in India, in China it is more; it is the life, for skin for skin, yea, all that they have will they give for it. The great mass of opium smokers earn, or have an income of, about twenty cents per day. Their opium costs them twelve cents per day, and while the wages or income may vary or cease altogether, the outgo must be forthcoming every day of every month of every year without variation (except it is increased) and without fail. No wonder dependent mothers and wives often commit suicide on learning a son or husband has taken to the drug.

I also used to think there was a difference between races in the reaction to its habitual use, and that the "native takes it increasingly up to a certain point, and does not then, as a rule, go beyond this for the rest of his life," though I knew the "rule" had multitudes of exceptions; but the tremendous increase in the sale of morphine to old opium smokers during the last few years proves that the tendency to increase is there just the same, so that now I firmly believe that in all respects opium acts on the Chinese just as it does on the Caucasian.

When taken in poisonous doses, and I have seen opium suicides by the score (we have a thousand a year in Soochow), the main symptoms are contracted pupil, slow respiration, congested face, followed by a pale, cold skin with profuse perspiration, itching skin, pulse fast and full at first and later rapid and feeble, dizziness and confusion followed by drowsiness, then irresistible tendency to sleep, unconsciousness, stertorous breathing, coma, and death. In medicinal doses it relieves pain, stimulates, is followed by drowsiness or sleep, contracts the pupil, slows respiration, etc., and morphine hypodermically, unless guarded by atropine, often causes vomiting, especially in women. If taken daily to get a constant effect, the amount has to be increased, and after a time the habit is established. Once established, the drug cannot be withdrawn without suffering. Cut off his supply and the victim becomes weak, seems utterly miserable, and is perfectly wild for the drug. In addition to the craving, if the drug is still withheld, some of the symptoms are myalgia, coryza, yawning, insomnia, diarrhœa, and seminal pollutions.

The habitués are constipated, some going to stool only twenty-four times a year, appetite poor, and as a matter of course they gradually become emaciated. In time they acquire the opium look that an experienced eye can detect, in nine cases out of ten without trouble, in any crowd met. As to strength, they are stronger immediately after indulgence, weaker later on, but the sum total is less than normal, and without their supply they are utterly worthless. I speak from experience, not theory. I have been carried by sedan-chair coolies for years. Nearly all coolies plying for hire in Soochow smoke opium, but enough of them refrain for me to know the difference. As to the moral character, we cannot see it as we can the physical man, but it is well known that an opium smoker will lie every time, and there is no meanness to which he will not stoop to get his drug, and no one wants to employ an opium-smoking servant.

The next point is that opium strengthens its votaries for "arduous labors." It may strengthen him temporarily, but the man who has to use opium in this way is borrowing capital. How about the time when he has to return it plus the interest? In China no one who desires arduous labor done ever sends for an opium smoker.

Again, Kipling claims that opium habitués are comparatively free from malarial fever. To this I will say, if they take it for this purpose so much the worse for the habitués. The remedy is worse than the disease. I would rather hear that a friend of mine had contracted malarial fever than that he had contracted the opium habit. The former might be cured, but the latter? If opium were surely prophylactic, so far from being an argument in favor of encouraging its use among an ignorant populace, it would be the strongest possible argument against it. If it were efficacious in all or a majority of cases, all would take to it and the last state of that people would be worse than the first.

If all the natives of India ate opium to prevent fever, I would be more ready to believe in its power, but so long as the majority of them refrain, "I hae ma doots." If it is a sure thing and a good, women and children ought to be encouraged to take to it as well as the men.

In claiming on one hand that the natives, after a certain time, do not increase their allowance, and on the other that the opium they take protects them from fever, Kipling overlooks the well-known law of opium that to get a constant effect its amount must be constantly increased. In our part of China it is not prophylactic, and the natives take it with no such idea. I treat thousands of patients, and lately have kept statistics on this point and found just as much malaria among smokers as among non-smokers.

Next we come to the statement of Sir William Moore. He urges in favor of opium that it "enables people to do on less food than they would otherwise require," but since the opium user loses so much time, two hours a day (to say nothing of being weakened by the drug, he cannot do as much work as he would otherwise do, and his opium costs six times more than the food he saves, I fail to see where the force of the argument comes in. He also says that crude opium "is certainly injurious, as it lessens both the secretions and movements of the stomach," the presumption being that opium (the article prepared and sold by the British government) does not do so and is not injurious. "Opium" (the British article) is glorious, o'er all the ills of life victorious. Crude opium (that raised and consumed without British revenue) stops the secretions and movements of the stomach and is to be avoided. How any man of his pretentions can speak of a "use" of opium outside of therapeutics is beyond my ken. What use can a healthy man have for a drug that lessens his appetite, constipates his bowels, and weakens his body?

As to the use of opium in aborting or checking malarial fever, I have tried and found it good as an adjunct of quinine, provided the patient is not addicted to the drug. This is the use and not the abuse of opium.

As to life-insurance statistics, I am examiner for all the companies in Soochow and know that they take Chinese only on the ten and fifteen year endowment plans, and they have not yet been operating in China long enough to get up reliable statistics, and I know, moreover, that opium smokers do not tell the truth as to the amount they consume.

The "good results" of the opium habit I have never seen and I have never questioned a native who ever said he saw them. The matter stands about like this:

FAVORING THE OPIUM HABIT.	OPPOSED TO THE OPIUM HABIT.
1. Opium dealers.	1. The bulk of the Chinese people.
2. The majority of the Eastern press (said to be owned or subsidized by the opium interests).	2. All qualified physicians practising largely or exclusively among the Chinese.
3. All other interested parties. This includes most Britishers, for their government is engaged in the opium business; and are they not interested in the honor of their government?	3. All missionaries.
4. Many globe trotters who know less about the question than the traveller who gives his impressions after a tour of three weeks knows of America.	4. Nearly all who have carefully investigated the subject on the spot. The assistant British judge in Shanghai has written as strongly against opium as any "rabid opponent": found, I think, in the report of the Blackburn commission, published about three years ago.
	5. I might almost add every foreigner living in China, for none of them—no, not even the opium dealers—will employ an opium-smoking servant.

If it "is frequently productive of good results," why are the Japanese (an Asiatic people) so unalterably opposed to it? When Count Ito, the man who made modern Japan, was in Peking last year, he told the high officials China would never amount to anything until she restricted opium. The editor of the Shanghai *Gazette* told me that during the Chino-Japanese war a number of Japanese coolies employed in Shantung contracted the opium habit, and the Japanese commander, rather than have them return to Japan, lined them all up and had them shot.

As to the "tolerance" established "through several gen-

erations," if the report of the commission sent to Sze-Chuen and Yunnan, where opium has been used most extensively for the longest time, of the devastation, poverty, and misery seen on every hand, is to be believed, the tolerance is that of the Irishman's horse for shavings seen through green spectacles: "By the time he got used to it he died."

In ugly fevers of irregular type, opium is useful as an adjunct of quinine, provided the patient is not addicted to the opium habit, but I should hate to have a fellow-practitioner called in consultation over one of my obstinate cases if I had used nothing but opium, and surely it is not necessary to make an opium fiend of a man in order to cure him of a fever.

As to the "moderate" use of opium, I have never been able to see where moderation ends and excess begins. All habitual users, whether taking a small amount or a larger quantity, are "opium devils," *i.e.*, slaves to the drug, and the suffering when trying to break the habit seems as great in the one case as in the other. Millions use alcohol in moderation without becoming inebriates, but not one in a hundred can dally with opium without becoming an opium fiend.

The idea that opium smokers are not so prone to disease other men are, is unsound in theory and, in my experience, has no foundation in practice. According to my statistics they are just as liable to malaria, rheumatism, and other diseases as other men are, and, moreover, are less resistant to the inroads of disease, less tolerant of injury, and less amenable to treatment. Fourteen men, victims of a tea-house collapse, were once brought to our hospital. Among them were two opium smokers, and although their injuries were not so serious, they gave more trouble than all the rest combined. The same is true of gunshot wounds and other injuries. If an opium smoker receives a serious wound, he generally is a goner. And in practice, how one is handicapped in trying to treat opium smokers! If they have pain, and in our part of China they are peculiarly liable to gastralgia and other "belly aches," what can one do for them? Our sheet anchor is of no use, and one feels as helpless as a babe. I have had them writhe in agony at my feet and have given one hypodermic of morphia after another, until I was afraid to go farther, without the least relief. Enemas do not often relieve, and as to cathartics, the patients are afraid of them, for fear they might cause diarrhœa. This same dread of "opium diarrhœa" hinders one at every turn in practising among the Chinese. We all know how often we feel like prescribing opening medicine in our practice, and yet I rarely write a prescription for an opium smoker without being cautioned by his or her relatives and friends against giving cathartics, and unless I can assure them the prescription contains nothing of the kind, or very little, they will not administer the medicine.

And suppose diarrhœa does supervene, then what? To give opium you might as well give aq. fontis and ditto any other medicine that I have ever used. The relatives, however, know what to do: they buy the coffin.

This question has a financial side, too, that it behooves the nations of the world to inquire into. The report I have referred to from Sze-Chuen and Yunnan says the natives there are, owing to the use of opium, unable to buy any foreign goods except a little cloth. Among all but the well-to-do, every man added to the ranks of opium smokers is a man (if he has a family, then the whole family) taken from the list of possible buyers of foreign products. What will be the condition of trade when opium is used as extensively everywhere else in China as in these two provinces?

And now I am going to tell you something you can print or not, as you like. Dr. E. R. Jellison, of Nanking, China, spoke of it in his answer to the questions for my book, but as the book was intended for promiscuous distribution, I did not think it well to print it. The inhibiting effect of opium is taken advantage of by the *demi-monde* to increase the attractiveness of their business. Smoked at the proper time the completion of the act can be delayed and sexual congress prolonged for, some say, two hours and maybe longer. Of course, if one pipe will do to-day, it takes two to-morrow, and in a few months the victim is an opium sot. All houses of ill-fame keep the pipe, and the youths who yield to their seductions are legion.

Nor is this use of it confined to houses of ill-fame. Many men use it for the same reason in their homes, and go on increasing the amount in order to get the effect until they smoke an ounce or more every twenty-four hours, smoking all night and not rising before 4 or 5 P.M. In a few years opium gets the upper hand, sexual desire ceases, the "little wives" become a burden, mutual recriminations ensue, opium suicides are the order of the day (I was called on to treat two of one man's wives in one month for opium poisoning), and the man is lucky if his wives do not leave him, or cohabit with some male servant, causing a scandal that is the talk of the city.

William Hector Park, M.D.

McMeekin, Fla., January 31, 1901.

THE NEW MEDICAL BILL.

To the Editor of the Medical Record.

Sir: In discussing the pending medical bill the Record seems to have assumed too broadly a rule: that unlicensed practitioners are not liable in damages for their malpractice. Any one who holds himself out as a physician incurs in his practice the same liability to which he would be subject were he what he falsely pretends to be. A clairvoyant was held to such liability in Nelson *v.* Harrington, a Wisconsin case, and a druggist in Matthei *v.* Woolsey, an Illinois case. It is true that if the non-licenciate pretends to belong to a particular "school" he will be held only to the standards of that school. Under the medical law of this State, as it now stands, many druggists have been convicted of the misdemeanor of illegal medical practice, and our statute is much more stringent than the law of England.

It is impossible to make a fool wise by legislation; and physicians—or some of them—seem at times to forget this principle, which the Cadi laid down in rendering judgment against the suitor who demanded damages of the veterinarian who had blinded him. "If you had not been an ass," said the Cadi, "you would not have gone to a horse doctor to be treated like a donkey."

May I ask in this connection a line of your space to correct a prevalent impression, growing out of my former connection with the County Medical Society, as its counsel, and what I have written of Eddyism—namely, that I am the framer of this proposed legislation. In fact, I have had nothing to do with it and have not even seen the bill. If it be a judicious measure, the credit is due to others; if it is open to criticism, the fault is not mine.

W. A. Purrington.

February 4, 1901.

THE THIRD PAN-AMERICAN MEDICAL CONGRESS.

(From our Special Correspondent.)

Havana, February 9, 1901.

The third Pan-American Congress, which has just concluded its sessions, greatly surpassed its predecessors in the character of the papers presented, and indeed there have been few meetings, national or international, of medical men in which so much work of a truly scientific character has been presented. The section meetings were held in the various halls of the university and of the adjoining institute for secondary instruction, while the three general sessions occurred, the first in the immense Tacón Theatre, the second and third in the Martí Theatre. The language of the congress was overwhelmingly Spanish, the only general address in English, except the opening speech of Governor Wood, being that of Dr. Wyman, of the Marine-Hospital service. In the sections, however, more English was heard, especially in the medical section, several sessions of which were devoted almost entirely to the discussion of yellow fever. The report of the convincing experiments of Drs. Reed, Carroll, and Agramonte excited the greatest interest, and there were few who heard the report but left the section persuaded that the disease is spread by the mosquito only, and that its germ must be a hæmatozoon one part of whose life cycle is passed in the body of Culex mosquito. Dr. Finlay, who presided over the section, was warmly congratulated upon the confirmation of the theory which he had enunciated many years ago. A number of the delegates made an excursion to Quemados to see the yellow-fever camp and the buildings in which the experiments were conducted. They were shown the mosquito house, the house where non-immunes had slept night after night on infected bedding without contracting the disease and without gaining immunity, as subsequent inoculation demonstrated.

Visits were also made to the Mercedes and other hospitals in Havana, and to the new bacteriological and histological laboratories of the University of Havana. These laboratories are being fitted up by Dr. Agramonte, formerly of New York, now assistant surgeon in the United States army, and also director of bacteriology in the University of Havana. This is the first time that bacteriology has been practically taught at the university, the teaching of this science having been hitherto purely didactic, owing to the absence of laboratories. An institute of bacteriology has been in existence for some years in Havana, but it was a private undertaking, and while doing excellent work was not available for the instruction of the students.

There were many interesting social events connected with the congress. On Monday afternoon General and Mrs. Wood gave a reception to the delegates and their families in the governor's palace. On Tuesday a visit was made to one of the most celebrated cigar factories.

On Wednesday the members with their wives and daughters were entertained by the Asociación Médica de Socorros Mútuos ("Medical Association of Mutual Succors," as the programme translated it) in what was formerly the Jané Theatre and is now a Baptist church. On Thursday a visit was made to the celebrated Morro Castle and the Cabaña fortress. On Friday, the congress having closed, many of the members made an excursion by rail to the sugar plantation "Rosario" at Aguacate, where they were shown all the processes of sugar-making and were entertained at breakfast by the owner, Señor Ramón Pelayo. In the evening of the same day there was a ball given at the Tacón Theatre in honor of the "Congressistas" by the city of Havana. On Saturday those of the members who had not left for their homes were entertained at breakfast by Señora Rosalía Abreu in the charming suburb Cerro.

It is rather a far call to Buenos Ayres, which has been selected as the place of meeting for the next congress, but if the congress is Pan-American the southern continent must, of course, receive recognition, and so the selection may be called a good one.

THE ORIGIN OF FIBROID GROWTHS OF THE UTERUS.

To the Editor of the Medical Record.

Sir: In the State Medical Society last week, after the paper by Dr. Charles A. L. Reed on "Infection," etc., the president of the society, Dr. A. M. Phelps, kindly invited me to speak. In my few remarks I dwelt on the anatomical and pathological changes in the tissues in consequence of infection; not only in the destruction of the normal tissue, but in the formation of new growths, malignant and otherwise. Many of these changes I had before demonstrated by a number of pathological studies, which from time to time I have had the honor of presenting to the profession.

On this occasion I should have liked to present to the State Medical Society my observations on the origin of fibroid tumors of the uterus. But to present the subject properly with its important bearings would have caused me to exceed the time limit for papers and made necessary a detailed exhibition of microscopical slides. My intention at that time was to place on record certain conclusions regarding the pathology of fibroid tumors of the uterus, preparatory to more elaborate explanations later. In a word, then, I wish to say that it is my belief that fibroid growths have their starting-points in the inflammatory products of the organ, and the different stages of development of fibroid tissue can be successfully traced on such a basis. I believe I have clearly proved this relation of cause and effect, which I trust to have an opportunity to explain more fully in the future.

Mary Dixon Jones, M.D.

RAPID CULTIVATION OF AND A DIFFERENTIAL STAIN FOR LOEFFLER'S BACILLUS.

To the Editor of the Medical Record.

Sir: In the *Wiener med. Wochenschrift*, No. 10, 1900, Prof. Luigi Concetti published his modification of the Neisser stain[1] for the bacillus of diphtheria. After questioning numerous colleagues interested in laboratory research, and finding that many had overlooked the article, I feel justified in asking you to devote this space to its publication.

Although I have not as yet accumulated enough material to warrant a report on the results of my examinations, I am convinced that it is an improvement over other methods now in vogue. The very excellent results obtained in the Pædiatric Laboratory in Rome should urge those interested in this branch of laboratory work to employ this method by which I believe the earliest possible bacteriological differential diagnosis is at present attainable. For the benefit of those who do not read Italian or German I quote in brief from Professor Concetti's article:

"A sterilized glass (or iron) rod is used, on the end of which is twisted a small piece of absorbent cotton impregnated with glucose glycerinated agar-agar. These rods are kept in sterilized test tubes. When a culture is to be made, the rod is removed, the affected part swabbed with the agar-agar end, and at once replaced in the tube. It is then deposited in a thermostat and kept at a temperature of 36° to 37°. In four or five hours enough bacilli will have developed to make a smear. It is stained with the methylene blue solution consisting of: Methylene blue, 1 gm.; alcohol, 20 c.c.; distilled water, 450 gm.; acetic acid, 50 gm. This solution must not remain on the slide for more than two or three seconds. It is then thoroughly washed with water. The smear exhibits an intense blue color. The counter-stain is now applied. It consists of vesuvin, 2 gm.; water, 1,000 gm. This solution is heated and filtered while still warm. The specimen should be exposed to the action of the vesuvin from fifteen to twenty seconds and then washed off in water. It displaces the methylene blue. If no true bacilli are present, the macroscopic appearance of the smear is altogether brown; in the presence of both true and pseudo-bacilli a blue and brown color is visible. The microscopic picture is as follows: The pseudo-bacilli are stained brown in their entirety; the bodies of the true bacilli stain brown, their polar ends, however, present characteristic blue points, the chief differential factor for diagnosis.

A. L. Goodman, Ph.G., M.D.

259 West One Hundred and Thirteenth Street,
New York City.

[1] Neisser's stain is described in an article on the "General Pathology and Bacteriology of Diphtheria," by William H. Park, "Twentieth Century Practice," vol. xvii.

TRAINING-SCHOOL FOR WOMEN EMBALMERS.

To the Editor of the Medical Record.

Sir: An institution long since needed in our city has at last been established. The desirability of having women perform the last rites for deceased persons of their sex can hardly be denied. The delicacy and modesty of women must often have been wounded when the thought occurred to them that immediately after death they are given into the hands of the undertaker to be prepared for interment or cremation, and that not some of their own sex attend to these last duties.

This school proposes to relieve this condition by educating women to do all the more delicate parts of the undertaker's work—in conjunction with him but not in his presence. This must surely be satisfying for the relatives of the deceased: the consciousness that gentle hands, directed by knowledge, are doing all that is demanded both by advanced civilization and the finer feelings of our nature.

The medical profession, in favoring and approving this step in advance, will be doing a graceful act of respect not alone for womanhood, but one in harmony with its noblest aspirations and duties.

Medicus.

Society Reports.

THIRD PAN-AMERICAN MEDICAL CONGRESS.

Held in Havana, Cuba, February 4, 5, 6, and 7, 1901.

(Continued from page 232.)

THIRD GENERAL SESSION.

Thursday, February 7th.

The third and closing general session was held in the Martí Theatre, under the presidency of Dr. Enrique José Varona.

Dr. Tomás V. Coronado, the secretary of the congress, announced that Buenos Ayres had been selected as the place of meeting of the fourth congress in 1904.

The treasurer, Dr. Acosta, then presented his report.

Dr. Curtin then read a memorial address on the late Dr. Pepper, the president of the first Pan-American Congress.

Sanitation and Quarantine.—Dr. Walter Wyman, surgeon-general of the United States Marine-Hospital service, read a paper dealing with this subject. His argument was the necessity of improving the sanitary condition of cities which, if effected with thoroughness, would enable us practically to abolish quarantine. It would be far more efficacious in the prevention of epidemics than any shotgun quarantine, or even than a concerted attack upon the focus of disease once this had become established. As it was now, the hold-up of a steamer at quarantine was almost always due to defective sanitation at the port of depart-

ure. The benefits that would result from the wiping out of all slums and other insanitary districts in any city were almost incalculable. It was recognized to-day, and to a degree acted upon, that the danger of the importation of infectious diseases came through the dwellers in the less cleanly portions of a seaport town. The marine hospital inspectors stationed in foreign ports examined the steerage passengers only, the cabin passengers undergoing no inspection. The orator then spoke of the changing views regarding the part bacteria played in the causation of disease. While essential to the production of infection, they were not in themselves sufficient to excite it. It was now recognized that the bacilli of disease often existed in healthy bodies and did no harm there. But let the individual's general condition become lowered by injurious external influences, and then the bacteria would at once begin to multiply and produce toxins, and their host present the symptoms of pneumonia, diphtheria, typhoid fever, tuberculosis, or other infection. Reverting again to the sanitation of cities, the speaker said that here was an opportunity for the wealthy to benefit their fellows by employing their capital in the tearing down of rookeries and erecting model tenements in their place. Regarding the efficacy of such operations he quoted from a paper read by Dr. S. A. Knopf, of New York, before the tenement-house commission, in which the absolute necessity of improved sanitary dwellings in the combat against tuberculosis was clearly demonstrated. One great difficulty in the way of the prevention of epidemics was, Dr. Wyman said, the foolish and criminal impulse of some municipal authorities to conceal the first cases of infectious disease, hoping that the latter would not spread, and dreading the inconveniences and losses that would follow the publication of such news and the resultant quarantine which would be established against the city. In his experience this culpable hiding of the facts was usually associated with neglect of sanitary matters. The dirtier a city was the more ready were its authorities to deny the possibility of any filth disease existing there. Regarding sanitary legislation, the speaker thought it was not peculiarly the province of the medical man, but rather the reverse. The physician was, as a rule, no better a legislator than he was a business man. After mastering the few essential elements of sanitation the lawyer, speaking generally, made the ideal sanitary legislator. Dr. Wyman was rather optimistic regarding yellow fever, believing that the time was not far distant when this disease could be made to disappear from Havana. The necessary means to this end were effective sanitation, good sewers, sanitation of the harbor, inspection of dwelling-houses, etc.

Dr. Vander Veer, of Albany, then delivered a brief address on behalf of the delegation from the United States, Dr. Charles A. L. Reed having been called home. He expressed the thanks of himself and his associates to Governor Wood for the interest he had shown in the congress and for all he had done to promote its success. He congratulated the physicians of Havana upon the sanitary condition of their city, upon the excellence of its water supply, etc. He extended thanks also to the executive committee for the nearly perfect arrangements, and to the ladies of Havana for their many kindnesses to the wives and daughters of the delegates. He had attended the two previous Pan-American congresses, and while there was evidence of good work done at both of them, he thought this was especially characterized by a vast amount of true scientific labor. These congresses had been organized for two special purposes: (1) The study of contagious, especially intertropical diseases; and (2) the study of the medicinal flora of the American continent. The first of these objects was being pursued in a thoroughly commendable manner, but the second was not. Of all the countries represented in the congress only one (Mexico) had made any appropriation for the furtherance of this object. It was not right that one country should meet the expense of a work that would benefit all, and he hoped material assistance would soon be given by the governments of the United States and other American countries.

Dr. Carlos Manuel García, of Mexico, then delivered a brief address, in which he dwelt upon the evils of alcoholism and urged concerted action by all the American governments looking toward its suppression.

Dr. Julio Lyón spoke in behalf of the profession in Santo Domingo, and Dr. Luis Debayle for Nicaragua and Honduras.

Dr. Varona then declared closed the third Pan-American Congress, in a brief address, thanking all the members for their contributions to the success of the congress. He said the Cubans looked upon them all as brothers, those of Latin America because they were of the same race, and those of the United States because of the part they had taken in giving to Cuba the inestimable boon of liberty.

SECTION ON MEDICINE.

Carlos A. Finlay, M.D., President.

At the opening of the session Dr. Finlay delivered his introductory address (see p. 201).

Prolonged Fevers of Nicaragua.—Dr. Luis H. Debayle, of Nicaragua, read an interesting paper on this subject. In his paper he went over the etiology, diagnosis, and treatment of these conditions. He stated that the principal characteristics of these fevers were that they were continuous, with variable remissions from time to time; that they were not typhoid in character; that they were prolonged for weeks and months; that they rarely presented renal, nervous, or cardiac complications; that they were nearly always accompanied by persistent constipation and loss of appetite; that they were very slightly influenced by quinine and antipyretics in general, and that in the blood the hæmatozoon of Laveran in one form or another was always found. He then went on to analyze the variations in the temperature, the character of the pulse, and the condition of the various other organs during this prolonged fever. As it was rarely followed by death, he had not had the opportunity to make post-mortem examinations. The diagnosis was at first extremely difficult, since it was necessary to differentiate it from various prolonged fevers, typhoid, bilious remittent fever, typho-malarial fever, and Malta fever. With this latter it had many points of similarity, but he did not believe that the cases he had seen could come under this category. It was true that these fevers were common in places where malaria prevailed and where typhoid was rare, but he believed that they were not cases of chronic malaria, and that the presence of the Laveran organism was only evidence of a double infection. In the treatment of these fevers antipyretics were of little avail; much less so was quinine, even when exhibited hypodermically or in large doses. What had given him the best results was the use of intestinal antiseptics and tonics. His conclusions were that this was a distinct fever, different from typhoid, bilious remittent, or other acute forms of fever.

Dr. Duplan, of Mexico, claimed to have observed in Tierres Callientes the same form of fever as that described by Dr. Debayle, and he was glad to note that other observers in another country had had the same experiences.

Dr. Martinez, of Havana, observed that the fever

described by Dr. Debayle was what was called in his country enterosepsia, and in his opinion was nothing more than Malta fever; and that some of these cases described by Dr. Debayle were light attacks of malarial fever, with an added infection of Malta fever. He claimed to have seen such cases in Havana.

Dr. Coronado believed that these fevers, as described by Dr. Debayle, were nothing more than prolonged remittent malarial fevers.

Dr. Calnek, in a practice of twenty years in Costa Rica, had observed the same forms of fever. He believed that this prolonged fever existed from Mexico to Panama.

Dr. Perna, of Cienfuegos, believed that these fevers were not confined to the tropics, and he remembered a description of a fever by Dr. Robert, of Barcelona, similar to this, and designated by him as simple infectious fever. He did not believe that they were paludic or malarial, on account of their benignity and because of the fact that they were not influenced by quinine.

Dr. Fernandez, of Puerto Rico, stated that he practised in a region where malaria was unknown, and that he had had occasion to observe many cases of this fever.

Dr. Guiteras stated that he believed he was the first to publish observations of this form of fever in the annals of the Marine-Hospital service in the United States, in the year 1881. He had described it under the name of "continuous thermic fever." He had formerly believed it was due to the disarrangement of the thermic centres, but had abandoned this theory when he noticed in Key West that this fever was transmissible; he then thought that it was an infectious fever. He had never found the hæmatozoon in the blood, and lately he was inclined to believe that they were cases of Malta fever, as he had recently seen in Philadelphia a case in an officer who had returned from Puerto Rico. In regard to secondary infections, a term so commonly used in this country, he did not believe that they were brought about by Coeligacitus, as this was a pyogenic organism, and the formation of abscesses was very rare in these cases.

Dr. Garcia Mon, of Havana, had seen many similar cases in the "Quinta de Dependientes," and had never been able to demonstrate the presence of the hæmatozoon in the blood. They never responded to quinine or intestinal antiseptics.

Dr. Debayle, in closing the discussion, said he had at first believed that these fevers were typhoid; in other cases that they were tuberculosis; in others that they might probably be cases of Malta fever. But he was convinced that Malta fever existed in Nicaragua, with its typical remission on the twenty-first day, while in these cases, which he had just described, the temperature was never remittent or reduced to normal. The symptoms were distinct from those of Malta fever. He intended to make new investigations in regard to this fever on his return to Nicaragua.

Fiebre de Borras.—Dr. Luis Perna, of Cienfuegos, read a paper on this subject. This disease, he stated, was a very grave fever. It usually attacked children, but could present itself in the aged. It was characterized by black vomit, either small in quantity or very abundant, which might come on immediately following the initial fever, or several days after. Very rarely was it accompanied by albumin, and never by epistaxis, melæna, hiccough, or icteric discoloration; it might attack the same person more than once; both whites and negroes were susceptible; it was malarial in origin, and consequently its rational treatment was by quinine. Analysis of the blood had always demonstrated the presence of the malarial parasite. It was different from yellow fever in that it was not contagious and was not accompanied by albumin, hiccough, epistaxis, or icteric discoloration.

Dr. Edelman, of Havana, was of the opinion that fiebre de Borras was a syndrome, and not a pathological entity. He had seen cases which were clearly those of yellow fever and others which were undoubtedly attacks of malaria. He had never observed cases due to typhoid fever nor profound lesions of the gastro-intestinal tract.

Dr. San Martin believed that fiebre de Borras was not a pathological entity but a symptom which might present itself in other fevers, as in yellow fever or malaria.

Dr. Dueñas was not going to discuss whether or not fiebre de Borras was what these fevers were, but would later on take up this subject in a paper which he was to read on the diagnosis of this disease in the native Cuban. But he wished to cite the fact that Kelock, Kierner, and Loupy had described the severe hemorrhages from the mouth which took place in the hæmoglobinuric bilious fever.

Dr. Moreno did not believe that fiebre de Borras was a paludic fever. He believed that fiebre de Borras was a form of yellow fever in natives. From the results of these discussions it was evident that the same difference of opinion existed now in regard to the duality of these two fevers, yellow fever and fiebre de Borras. Many native physicians were of the opinion that it was a peculiar fever which attacked children; others that it was a form of malaria, others that it was a symptom of various conditions, while the majority believed that fiebre de Borras was the yellow fever in the native.

The Etiology of Yellow Fever, an Additional Note.—Drs. Walter Reed, James Carroll, and Aristides Agramonte, United States army, presented this paper, read first in English by Major Reed and then in Spanish by Dr. Agramonte. The following is an abstract:

"In the preliminary note read before The American Public Health Association at its meeting at Indianapolis, Ind., October 22 to 26, 1900, we arrived at the conclusion, based on observations made by us, that the mosquito was the intermediate host for the parasite of yellow fever.

"In this additional note we present the results of our further investigations on this important subject, which we have continued at an experimental sanitary station (Camp Lazear) near the town of Quemados, Cuba.

"At this station, in strict quarantine, and with every source of infection absolutely excluded, we have succeeded in infecting 85.71 per cent. of those individuals who have been bitten by purposely contaminated mosquitos (Culex fasciatus). Our observations do not conform with the opinion that mosquitos carry the specific agent in their proboscis, and simply transfer it from one individual to another in a mechanical way, but appear to demonstrate that the parasite of this disease must undergo a definite cycle of development in the body of the mosquito before the latter is capable of conveying infection. This period would seem to be not less than twelve days.

"We also consider in this paper the question of house infection, and are able to show that this infection is due to the presence of mosquitos that have previously bitten yellow-fever patients; and that the danger of contracting the disease may be avoided in the case of non-immune individuals, who sleep in this building, by the use of a wire screen.

"We also demonstrate by observations made at this camp that clothing and bedding contaminated by contact with yellow-fever cases, or by the excreta of these patients, is absolutely without effect in conveying this disease.

"Conclusions: 1. The mosquito (Culex fasciatus) serves as an intermediate host for the parasite of yellow fever.

"2. Yellow fever is transmitted to the non-immune individual by a mosquito that has previously fed on the blood of those sick with this disease.

"3. An interval of about twelve days or more after contamination appears to be necessary before the mosquito is capable of conveying the infection.

"4. The bite of the mosquito at any earlier period after contamination does not appear to confer any immunity against subsequent attacks.

"5. Yellow fever can also be experimentally produced by subcutaneous injection of blood taken from the general circulation during the first and second days of this disease.

"6. An attack of yellow fever, produced by the bite of the mosquito, confers immunity against a subsequent injection of the blood of an individual suffering from the non-experimental form of this disease.

"7. The period of incubation in thirteen cases of yellow fever has averaged from forty-one hours to five days and seventeen hours.

"8. Yellow fever is not conveyed by fomites and hence disinfection of articles of clothing, bedding, and merchandise, supposedly contaminated by contact with those sick of this disease, is unnecessary.

"9. A house may be said to be infected with yellow fever only when there are present within its walls contaminated mosquitos, capable of conveying the parasite of this disease.

"10. The spread of yellow fever can be most effectually controlled by measures directed to the destruction of mosquitos, and the protection of the sick against the bite of these insects.

"11. While the mode of propagation of yellow fever has now been definitely determined, the specific cause of this disease remains to be discovered."

Dr. Perna said we must not fall into the error of "post hoc ergo propter hoc," an error already made by Carmona, Freyie, Sanarelli, and others; we must not be too precipitate in accepting the result of statistics. The studies made of mosquitos were very old, and he stated that a French physician, who died about the year 1850, had expressed the opinion that malaria, yellow fever, and cholera were propagated by mosquitos. Dr. Perna also criticised the methods employed by the commission in making experiments on human beings, and stated that he was entirely opposed to such experiments.

Dr. San Martin defended eloquently and with strong arguments the high scientific standard of the experiments as carried out by this commission, and also brought out the point that it was not statistics but facts that this commission presented.

Dr. Holbeck, of Charleston, S. C., was particularly interested in the paper, and expressed his opinion that the problem of two hundred years was about to be solved, and that the old quarantine regulations should be greatly modified. He also described the existence of a pine belt within a short distance of the city of Charleston, in which yellow fever never developed as an epidemic, although patients with the disease would go there during the existence of an epidemic in Charleston, would die from the disease, and yet it would not spread. Mosquitos were not known in that region, and probably this was the true explanation of the above fact. He concluded by emphasizing the inestimable value of these experiments if they should prove to be true.

Dr. Martinez enforced Dr. San Martin's views. He took up the moral question and claimed that without these experiments no truth could have been found.

Dr. John Guiteras, who up to within a short time had opposed the theory of the transmission of this disease by mosquitos, now accepted as incontrovertible the results of the experiments of the commission. He had followed with interest many of the experiments, and as a member of the commission saw most of these cases which he had no hesitation in pronouncing typical cases of yellow fever. A fact which impressed him forcibly was the absolute control of the epidemic by Dr. Reed. The cases would develop or not as he wished. He did not think that the mosquito should be called the Culex fasciatus. Giles' description of the Culex tiniado mosquito agreed more closely with it than with the Culex fasciatus. He described the difference between them. He was inclined to consider the yellow-fever mosquitos as belonging to a genus apart, because they laid eggs different from the other form of Culex.

Dr. Finlay expressed his admiration for the work of the commission. He said that he believed that this session of the congress would go down in history as one of transcendent importance. He believed that the differences between his opinion and that held by the commission would disappear in the course of time. He stated that they were based upon the fact that he experimented with three varieties of mosquitos, while the commission had been restricted to one variety; that the board was placed upon a better footing for obtaining satisfactory results; that the negative result obtained by the inoculation of mosquitos of short infection should not induce the commission or the board to make such hard-and-fast rules as were evidenced in its conclusions. The mosquito theory, so far as he was able to trace it by personal efforts, might be said to have reached only its evolutive stage, awaiting the absolute confirmation of some of its essential points.

Dr. Reed, in closing the discussion, said that he was profoundly impressed with the interest and attention given to these experiments. In regard to the moral aspect of the case, he did not think that any one appreciated the position in which he found himself; the difficulties that beset his path. The first experiment was made on a member of the board, Dr. Carroll. The senior member of the board expected to take his bite in turn, but was unexpectedly called north. As no animal could be given the disease and it was useless to follow the previous indefinite experiments, it was absolutely necessary to make these experiments on human subjects, or otherwise volumes could have been written and discussed and yet we should have been no nearer the truth than at first. No progress could have been made toward an exact knowledge of the disease unless human subjects had been used. All experiments were performed upon persons who had given their free consent. In reference to the remarks of Dr. Holbeck, of Charleston, he simply stated that the disinfection of vessels should by no means be dispensed with, but only that of such articles as bedding and clothing; it was necessary to get rid of the mosquitos and this simplified the process of disinfection. In regard to the remarks of Dr. Guiteras in reference to the name of the mosquito, Dr. Howard, of Baltimore, had told the speaker that Culex fasciatus was identical with Culex tiniado as described by Giles. Theobolt separated Culex tiniado from the genus Culex and placed it in a new genus Stegamina. These laid their eggs in a peculiar way, and there was also a difference in the anterior claws of the male insect from those of the other Culex. There was also a difference in the larva of the Culex fasciatus. It was very interesting, too, to note the fact that this was the very mosquito that Dr. Finlay used in his experiments; and if this particular mosquito did not belong to the genus Culex, we found that malaria had a genus of its own (Anopheles) and yellow fever the genus Stegamina.

(To be concluded.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 7, 1901.

ROBERT F. WEIR, M.D., PRESIDENT.

The Late Dr. Horace Green.—DR. D. B. ST. JOHN ROOSA presented to the academy, on behalf of Mrs. Green, a bust of the late Dr. Horace Green. He said that according to laryngologists of note this man must certainly be looked upon as an eminent pioneer, one whose place in medical literature could never be effaced.

Conservative Operations upon the Uterine Appendages.—This was the subject selected for this evening's discussion, and presented to the academy under the auspices of the section on obstetrics and gynæcology.

Their Technique.—DR. J. RIDDLE GOFFE opened the discussion by the consideration of this topic. He said that one of the simplest of the operations to be considered that evening was the opening of the posterior fornix and the breaking up of adhesions. Perhaps the next simplest procedure was the opening of cysts of the ovaries. The next step would be to remove the diseased portions of the ovary and at the same time preserve the remaining portions. This was done by taking a slice from the organ. Professor Clark, of the University of Pennsylvania, had recently demonstrated to the New York County Medical Association the marvellous vascular supply of the ovary. This consisted of a system of freely anastomosing vessels, thus allowing of considerable injury to portions of the ovary without sacrificing the vitality or function of the remaining portion. Attention was called to the anatomy of the broad ligament and to the analogy between the arrangement of the blood-vessels and of the peritoneum in connection with the intestine and with the ovaries and tubes. In a case of pyosalpinx, when it was desired to resect a portion of the tube, the first step was to control the blood supply of the distal portion of the tube by quilting up the tissues by the insertion of sutures, and then an oblique section was made. To keep the mouth of the tube patulous an operation was then done on the stump of the tube, which was similar in some respects to that of circumcision. Referring to ovarian transplantation the speaker said that, of course, the chief object of all such work was to preserve to the woman the menstrual experiences, and thus save her from many of the distressing nervous disturbances that followed the removal of both ovaries.

The Significance and Importance of Such Conservative Operations.—DR. WILLIAM M. POLK discussed this subject. He said that the importance of such work was self-evident, but surgeons had been slow to adopt such methods because they were loath to leave behind in a tissue like the peritoneum any disease which might perhaps jeopardize the life of the patient. Now that the propriety of conservative surgery in this field had been demonstrated, the importance of such work increased with the extent of the new field opened up. The cases presenting themselves for this class of work naturally divided themselves into two great classes, viz.: (1) Those resulting from sepsis, and (2) those due to specific infection. The speaker said that the circulation of the ovary, like that of other glandular structures, was so jealously guarded that there was no reason why all of the ovary should be sacrificed because a part happened to be diseased. But unfortunately the surgeon did not know the kind of cysts in the ovary which would remain quiescent, and until in the position to decide this point one could not predict with certainty the results of allowing such formations to remain. In spite of this it seemed proper for the surgeon to advise conservative surgery on the ovary in women within the child-bearing period. This policy would probably give the greatest symptomatic relief in the largest proportion of cases. In his opinion, one was justified in doing a plastic operation on the ovaries for the sole purpose of promoting maternity.

The Immediate and the Remote Results in One Hundred Cases.—DR. W. L. BURRAGE, of Boston, read this paper. Three of his patients, out of one hundred and fifty-six, died as a result of operation. One of the cases was a colpotomy with secondary hemorrhage; the second was an ectopic pregnancy; the third a case of multiple operations for adherent retroversion and salpingitis in a greatly debilitated person. Some of his patients had had a good deal of pain after resection of the ovary, and many of them had also exhibited a temporary enlargement of the ovary. As these symptoms had not been observed so frequently in his more recent cases, he was inclined to attribute them to imperfect hæmostasis after free puncture of cysts. It should be borne in mind that conservative operations generally required a somewhat longer time than other operations for their performance. His general rule was not to do more than could be accomplished within two hours, the total time the patient was under ether being of great importance. An instance had been reported in literature in which an abdominal pregnancy had occurred in a case in which the uterus had been extirpated, leaving one ovary and tube. A symptomatic cure had been noted in 73 out of 100 cases, and an anatomical cure in 44 out of 69 cases in his practice. It should be noted that 34.5 per cent. of the women who had previously borne children had become pregnant after the operation. In no instance had pregnancy occurred after resection of a closed tube, both tubes being closed at the time of operation. Out of 85 cases, in only one, a syphilitic, was another operation necessary because of subsequent enlargement of an ovary from cystic disease. In 7 other cases, cystic at the operation, it had been noted that enlargement had taken place subsequently. As far as could be determined, the amount of ovarian tissue present bore no definite ratio to the amount of menstrual flow or to the degree of sexual desire retained. When the tubes were open at the time of operation pregnancy was common after operation, even though only a small fragment of ovary was allowed to remain. A case was reported in which pregnancy had occurred twice after an operation in which both tubes and one ovary had been removed. He had carefully removed both of the tubes at the operation, hence the pregnancy must have occurred without the intervention of a tube.

DR. ROBERT F. WEIR commented upon the remarkable success that had attended the efforts of the gynæcologists to unite divided Fallopian tubes, and said that this was in striking contrast with the poor results achieved by general surgeons in their attempts to unite the vas deferens and the urethra when accidentally divided.

An Experience in One Hundred and Eighty-Two Similar Cases.—DR. A. PALMER DUDLEY presented a *résumé* of his experience in these cases. He said that conservative surgery, as already presented this evening, was really much more radical and dangerous than that kind of surgery which one was wont to call radical surgery. It was conservative in the sense that it preserved certain functions to the woman. He had been working in this field for twelve years, and in all that time had felt justified in selecting only one hundred and eighty-two of his cases for this kind of surgical work. It was believed that the circulation had everything to do with the results of conservative work. Many of these women would never have come under the knife had there not been some disturbance of the

circulation of these organs. He personally preferred not to use the cautery in the treatment of ovarian cysts, for no one could tell how far the destructive action of the cautery might extend; he preferred to open the cysts and destroy the sac without injuring any other portion of the ovary. The life of the ovary depended upon its vascular supply, and that was why cystic degeneration was so much more extensive on the upper surface. In former years it had been customary to apply to the tubes a catgut ligature which actually and completely closed them for only a few days. His own belief was that the reason pregnancy could occur when there was only half a tube was that by a suction action of the pelvic floor the blood serum, which was found normally in the pelvis at each menstrual period, was carried into the uterus, and along with this the ovum was conveyed into the uterine cavity. He had records of one hundred and twenty-nine cases in which the patients had been cured of all symptoms and restored to health. Plastic work on the ovary had been done one hundred and twenty times. He had learned of twenty-seven pregnancies having occurred since operation, twenty-two of which had terminated in the birth of living children. In six cases he had done ovarian implantation—not ovarian transplantation. By implantation he meant that he had cut a V-shaped piece out of the ovary to reduce its size, and had then implanted it into the fundus of the uterus in such a manner that it protruded into the uterine cavity. In every one of these six cases the menstrual function had been re-established. Dr. Dudley said that at the International Medical Congress in Amsterdam in 1889 he had reported his first case of ovarian implantation, and had asked the world to produce any similar case, but there had been no response. In a recent article in the MEDICAL RECORD a writer had made the statement that he had, in years gone by, done this operation of ovarian implantation, but in spite of this assertion he had as yet failed to give the date of his operations of this kind.

Some Drawbacks to Conservative Surgery.—DR. H. C. COE commented upon the fact that some of the surgeons who not many years ago were removing tubes and ovaries which did not seem to show any evidence of disease, were now clamoring for conservative surgery on the uterine appendages. For about five years past he had been constantly practising conservative surgery in this field, but he had never felt that he could do this properly by the vaginal route. It was important, after such work, that the appendages should be fixed in their normal position by suture, and this necessitated abdominal section. There were some drawbacks to this conservative work. It was very simple, of course, to separate adhesions, but he did not believe it was always possible to prevent them from re-forming, as was proved by the secondary operations on cases which had had an ideal convalescence after the first operation. In former years a few cysts on the surface of an ovary had been enough to condemn it, yet we were not in a position even now to decide between harmless and harmful cystic formations. Operations on the tubes, as Dr. Dudley had said, required the exercise of good judgment, and it was probable that his bad results in this class of cases were to be explained by an absence of that good judgment and that large experience so necessary to achieve success in this particular field. In several of his cases of conservative surgery there had been a return of the symptoms, and in only one or two had pregnancy occurred and gone to term. In three cases cysts about the size of an orange had developed in the portion of ovary that had been allowed to remain. According to his experience, women were not so extremely anxious to become pregnant as they were to be rid of the symptoms for which they sought relief. It seemed, therefore, that the patient should have sufficient confidence in the surgeon to leave to him the wisdom or unwisdom of practising conservative surgery in a given case. Women were often greatly delighted to learn that a portion of ovary had been left behind, but if subsequently they experienced the old pain they were sure to think that this piece of ovary was the cause, and would bitterly upbraid the surgeon for having left it.

DR. H. J. BOLDT included among the cases in which conservative surgery might be practised cases of ovarian cystoma. The use of the cautery seemed to him a necessary supplement to puncture of small ovarian cysts.

DR. E. H. GRANDIN was doubtful if the word "conservative" was the proper term to apply to the class of surgery under discussion. In the cases in which he had tried it he had either had to operate again or the women had pestered him time and again because of symptoms which he had failed to relieve by the operation. He had been unable to follow his hospital cases, but he could recall a number of cases in private practice which had not yielded satisfactory results under this so-called conservative management. Some of these women had menstruated, it was true, but they had done so irregularly, and at times profusely, and they were disposed to ask why he had allowed it to continue. Until the gynæcologist was able to differentiate the cases upon which it was safe to practise conservative surgery he would not be in favor of such work. He hoped that that knowledge would be eventually in our possession, but certainly it was not ours at present. In many of the multiple operations reported this evening he was disposed to think that the good result had not been dependent upon the conservative surgery practised on the appendages, but rather to some of these other operations.

DR. PHILANDER A. HARRIS, of Paterson, was disposed to think there was a very happy medium between the conservatives and the radicals. Photographic records were presented to illustrate the character of his own work in this field.

DR. H. N. VINEBERG remarked that unless the gynæcologists could actually prove their ability to do conservative surgery successfully, they really had no right to exist. His experience corresponded quite closely with that given by Dr. Burrage. Many of the speaker's patients belonged to a class in which the question of child-bearing was one of very great moment; hence he had been compelled to resort to conservative methods very largely. In most of these cases the disease had extended to the appendages from the uterus, and it was the condition of the uterus itself which he thought would demand more careful consideration in the future.

The Auscultation of the Normal and Pathological Muscle Sound.—Max Herz has studied the auscultatory phenomena attending the contraction of muscles and thinks that some diagnostic value may be attached to the sounds so produced. If the ear be applied to a contracting or contracted muscle a sound will be heard resembling the first heart sound in character and intensity. It may easily be elicited by having the patient stand on tiptoe, and auscultating the calf of the leg, either directly or with the stethoscope. Another method is to let the patient pull with both hands at either end of a towel looped behind his neck. The sound is so loud that it is not necessary to lay bare the skin. While the author has not yet been able to formulate any distinct conclusions, he has observed marked variations in the nature and intensity of the sound in different pathological states, and doubtless further study will bring some interesting facts to light.—*Centralblatt f. innere Medicin*, January 5, 1901.

THE NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 9, 1901.

EUGENE HODENPYL, M.D., PRESIDENT.

Diffuse Gangrene of the Lung.—DR. LEON T. LE WALD presented several specimens. The first one was from a case of diffused gangrene of the lung. Nearly the whole of the lower lobe was found to consist of a soft greenish mass. Rupture had occurred into the pleural cavity, and the latter contained several ounces of dark greenish fluid. The patient was a man twenty-six years of age, who had been admitted to Bellevue Hospital on December 19th. On admission, a few moist râles had been found over both lungs, and his temperatures had been 103° F. A diagnosis of bronchitis was made. The urine contained a trace of albumin, had a specific gravity of 1.020, and was free from sugar. The next day the temperature was 99° but quickly rose to 104°. On the third day the man had a chill with a temperature of 105.4°. Eight hours later it had dropped to 98°, and again rose to 103° after a second chill. On the fourth day the sputum became offensive. The diagnosis of gangrene of the lung was made. Dulness was present over the upper portion of the lower lobe of the left lung. The temperature remained at about 104° for the next four days. Death occurred on December 26th. Examination of the blood at the time of admission showed a leucocyte count of 7,650. On December 20th the leucocyte count had been 22,000. Aside from the gangrene of the lung the autopsy showed evidence of septic infection. The spleen weighed two pounds two ounces, and was very soft and pale. The liver and kidneys showed parenchymatous degeneration. The lung was stained with eosin and methylene blue, but no cultures were made.

Death from Lodgment of a Plug of Tobacco in the Bronchi.—The second case was one in which death had resulted from the inhalation of a large piece of tobacco. A man, twenty-five years of age, had been found dead in a stable. The autopsy showed signs of asphyxiation. On removal of the lungs the piece of tobacco was found completely blocking both bronchi and extending up into the trachea.

A Case of Thrombosis of the Subclavian Artery.—The third case showed thrombosis of the left subclavian artery at a distance of one inch from the aorta. This had resulted in a dry gangrene of the arm extending up as far as the middle of the upper arm. The clot was formed on an isolated atheromatous patch. The patient was a man fifty-five years of age, and death had resulted from a septic broncho-pneumonia.

DR. HODENPYL remarked that the peculiar odor of this lung would lead one to suspect actinomycosis, but there was nothing else about the specimen to suggest this.

Advanced Fatty Change of the Heart.—DR. E. K. DUNHAM presented specimens from a case of advanced fatty change of the heart. The heart-muscle fibres from this case contained a great amount of fat. He had studied the case carefully to determine the relative amount of fat to the cell body. A diagram was shown, drawn to scale, of the heart-muscle fibre, the portions representing the fat drops having been cut out and weighed. It had been found in this way that about one-third of the area of the cell section consisted of fat. Measurements went to show that the area of the cell section was two and a half to three times that of the normal cardiac muscle fibre, so that the increase in the size of the cell was greater than the addition of fat. This raised the question as to whether this might not be an infiltration and not a degeneration. From these measurements there was certainly no reason for supposing that the fat was due to degeneration; on the other hand, fatty infiltration seemed quite a reasonable explanation in the light of these measurements. It was agreed that fat might be derived from proteids, because it was known that carbohydrates could be so derived. But the carbohydrates were so much more easily burned that it was probable that a large quantity of the fat in such cases represented a food-residue not readily oxidized and, in this sense, to be regarded as an infiltration. The case was one of very marked anæmia supposed, before death, to be pernicious anæmia, occurring in a person of forty years of age, but might have been one of secondary anæmia due to advanced interstitial nephritis. The accumulation of fat in these heart-muscle fibres was probably the result of a failure to burn the fat readily owing to the anæmic condition. Three sections from this case were exhibited under the microscope.

Congenital Absence of the Kidney.—DR. OTTO H. SCHULTZE presented specimens from a man about thirty years of age, of whose clinical history nothing was known. The cause of death had been clearly shown to be an acute lobar pneumonia involving the upper and lower lobe of the right lung. The point of interest was the absence of the left kidney. A little above the level of the sacro-iliac synchondrosis was a vestige which was taken to be the "anlage" of the kidney and ureter. By this term was meant not only the site but the actual tissue which should have developed into a given organ. This vestige consisted of a canal in which there was a distinct bend. The upper portion was dilated into an ampulla composed largely of connective tissue with here and there a canal. Under the microscope this canal resembled closely a well-developed ureter. Above this enlargement were three canals branching off and passing externally to the ampulla. They were about 6, 5, and 3 cm. in length respectively. On cross section a number of canals could be found, and these were lined with cuboidal epithelium. The contents consisted of dark brown material which was shown under the microscope to consist of epithelial detritus. This duct he took to be the ureter, and the division as having taken place before the formation of the kidney. Surrounding this tube a fascia or sheath, passing from the brim of the pelvis into the true pelvis and inguinal canal, apparently connected with the tunica propria of the testicle. The testicle and epididymis were present, but they did not occupy their normal relations, the epididymis being stretched out above the testis. The tunica vaginalis testis passed upward and included the tail of the epididymis. From the latter a very thin duct could be traced upward; it was apparently the vas deferens, but was lost at the bladder wall. On dissecting up the peritoneum the vas deferens and vesicula seminalis with the ejaculatory duct were seen on the right side. The seminal vesicle on the left side was not nearly so well developed. The orifice of the right ureter was quite distinct; that of the left ureter could not be found, nor could any trace of the left ureter be discovered at the bladder. This was because the left ureter passed upward upon the bend mentioned, becoming atrophic. Sections of the ureter had been made in various places, and of the right and markedly hypertrophied kidney. The size of this kidney was apparently due to compensatory hypertrophy.

DR. DUNHAM asked if the recurrent portion of this ureter had been examined microscopically.

DR. SCHULTZE said that this portion had not as yet been examined.

Cases of Primary Malignant Neoplasm of the Lung and Pleura.—DR. I. ADLER presented specimens taken from a man twenty-five years of age, who

had entered the hospital with symptoms of obstruction of the upper part of the cava. Soon afterward symptoms indicative of obstruction of the lower part of the cava also were developed. There was a large area of flatness over the right chest. The heart was displaced toward the left, and puncture showed no fluid. A diagnosis of primary malignant neoplasm of the right pleura had been made. The man had been absolutely well up to a few weeks before coming to the hospital, yet death had occurred about two weeks after admission. The autopsy had verified the diagnosis of such a tumor involving the mediastinum and causing pressure on the cava. The tumor peeled off quite readily from the sternum, leaving intact bone and fibrous tissue beneath. The tumor mass filled the anterior portion of the chest, and the lung was compressed upward and backward toward the spine. The diaphragm was displaced downward and the anterior mediastinum was filled with these masses. The upper cava was almost completely obstructed by the pressure of the growth; the lower cava was obstructed but not to the same extent. The left lung was normal. With the exception of a few secondary deposits in the liver this organ was normal.

Dr. Adler presented a specimen from a second case of this kind. It had been taken from an old man who had been admitted to the hospital with a diagnosis of pulmonary consumption. He had not seen the man during life. At the autopsy the upper portion of the left lung was found to be made up of a tumor mass of soft and friable nature, and involving the pleura. Toward the apex the lung was more or less infiltrated with tumor substance. The lower lobe was nearly free, and the right lung was completely free. On section of the lung the invading mass was shown not to be fibrous but distinctly tumor tissue.

The third case presented had come under observation only a few weeks ago. The patient was a man about sixty-seven years of age, who had been well up to two months before admission to the hospital. At that time he had begun to fail in health and strength, and complained of some pain in the right chest and of difficulty of breathing. He was extremely cachectic and feeble. There was complete dulness of the anterior portion of the right thorax; the heart was displaced to the left and its action was very feeble. There was absolute flatness over the anterior part of the chest. There was an area of tympanitic percussion note with lung resonance in the upper portion of the right thorax, and an area of well-marked dulness about half an inch wide extending across the chest, and again an area of tympanitic resonance, and again an area of absolute flatness. Here auscultation revealed no respiratory sound. The area of dulness gave diminished respiration with a few râles and considerable friction. Anteriorly there were no respiratory murmur and no vocal fremitus. It had been assumed that there was fluid in the chest, chiefly low down posteriorly, and that the area of dulness between the tympanitic areas was due to tumor infiltration originating in the pleura. In addition, it was thought that there were metastatic deposits in the lung itself and some hemorrhagic effusion. The autopsy confirmed this diagnosis. Neither the aorta nor the heart was affected by the surrounding mass of new growth. There were a few secondary deposits in the liver and in the right kidney. The left adrenal had been converted into a huge mass of tumor tissue.

The fourth specimen presented by Dr. Adler had been taken from a man whom he had seen quite frequently for a number of years in the practice of Dr. Lewengood. The man had appeared exceedingly healthy, but was annoyed by a persistent cough and by some pain in the left apex. Examination had shown absolute dulness at this apex with absence of respiratory and vocal sounds. There was also bloody expectoration, and this had been repeatedly examined microscopically but with negative result. A diagnosis of tumor had been made quite early because this dulness had crept steadily backward. Death had occurred from a sudden and profuse hemorrhage. The autopsy had revealed a very thick pleura, which the microscope showed to be due to tumor tissue. There was considerable tumor tissue around the pericardium and the latter was very much thickened. Some of the tumor tissue grew into the heart. There were a few small metastatic deposits in the liver, the kidney, and the bronchial glands.

Commenting upon these four cases, Dr. Adler said that all of them had presented the same features under the microscope. These were illustrated by several drawings. All of these tumors were really endotheliomata. There had been considerable discussion on endothelium and epithelium, and their very similar structure. Waldeyer was inclined now to call the covering of the serous membranes epithelium, but it would seem that the name endothelium should be restricted to the lining of the lymph channels, the covering of the blood-vessels, and the lining of the blood capillaries. His own studies had led him to this conclusion long ago. When he said that these tumors were endotheliomata he had meant that they originated from the pleura and from the pleura alone, and that the cellular portions had originated in every one of these cases from the lining of the lymph channels. These growths had not originated from the epithelium of the free surface of the pleura or from the tissue of the lung. Wherever the lung in these cases was seen affected the involvement was secondary. From the studies that he had been able to make and from a careful examination of the literature he was inclined to believe that primary tumors of the lung originated only from the bronchial tract, from the epithelium of the bronchial surface, and especially from the epithelium of the bronchial mucous glands. They were in every case carcinomata. All the other tumors which did not originate from the bronchial surface or from the bronchial mucous glands originated from the pleura, and were all endotheliomata in the sense already mentioned. As such they must be classed among the fibrous-tissue tumors, and in close proximity with the sarcomata. The alveolar portion of the lung had thus far not been shown to be the seat of a primary tumor.

Cerebellar Abscess; Rupture into the Fourth Ventricle.—Dr. George P. Biggs presented a specimen of cerebellar abscess taken from a man forty-one years of age, who gave a previous history of defective hearing since the age of twelve years, following an attack of scarlet fever. Discharge from both ears has occurred at intervals, the last time being two months before admission to the hospital. Eleven days before admission he had been seized with severe pain in the back of the head, with vomiting and with partial paralysis of the right side of the face. His chief complaint was headache. On admission he was apathetic and in poor general condition. There were paralysis and impaired sensation and touch on the right side of the face, and the tongue deviated to the left. The left pupil was larger than the right, and both reacted to light. The neck was rigid and tender. There were nystagmus, and conjunctivitis of the right eye. The pain in the head continued to be severe, and was associated with delirium. Death occurred three weeks after the onset of the acute symptoms. During the last few days of life hiccough was very persistent. The temperature varied from 100° to 103.6° and the pulse between 90 and 105. At the autopsy a meningitis was found at the base, and particularly over the right lobe of the cerebellum.

Around the seventh and eighth cranial nerves on the right side was considerable purulent exudate, and these two nerves were distinctly softened. The lateral ventricles were moderately distended with sero-purulent fluid, as was also the third ventricle. In the fourth ventricle, which was considerably distended, were some offensive pus, and a pyramidal-shaped mass of necrotic material measuring 2 cm. in length and 1.5 by 1 cm. at the base. This mass of necrotic tissue had originated in an abscess in the right cerebellar lobe close to the pons. A communication had been established between the fourth ventricle and this cavity by a rounded opening measuring 1.5 by 1 cm. The abscess cavity was pyramidal in shape, with the base looking back toward the ventricle and its apex forward toward the middle peduncle. There was also a small perforation at the anterior extremity of the abscess cavity. The cavity measured 3 cm. antero-posteriorly, 2 cm. horizontally, and 1.5 cm. vertically. The floor of the fourth ventricle was covered with a thick layer of greenish and offensive pus. The petrous portion of both temporal bones was thickened, and on the right side there was a quantity of offensive pus. The smooth rounded opening between the abscess cavity and the fourth ventricle suggested a process of some duration.

Splenic Tuberculosis of Unusual Type.—Dr. Biggs also presented specimens from a case of general tuberculosis, occurring in a colored child of nine years. The interesting feature was the tuberculosis of the spleen, which was very extensive and was characterized by firm, gray tuberculous nodules of unusually large size, having the appearance on first inspection of tumors. The spleen weighed 280 gm. and the nodules were $\frac{1}{5}$ to $1\frac{3}{4}$ cm. in diameter. Microscopical examination showed extensive caseation, and but very few giant cells. In other parts of the body the tubercles also showed a tendency to grow to an unusual size, and to be the seat of extensive caseation.

A second specimen exhibited was from a colored man fifty-three years of age, with a history of tuberculosis extending over five years. The tuberculous process was quite general throughout the body. The spleen was very large and intimately adherent to the surrounding tissues. It weighed 1,010 gm. In this spleen were very large groups of miliary tubercles very closely aggregated, forming firm grayish areas $\frac{1}{2}$ to 2 cm. in diameter. Microscopically these areas showed the usual structure of miliary tubercles with many giant cells, a pronounced tendency to the formation of fibrous tissue, and but slight coagulation necrosis. The same features were noted in the tuberculous lesions of other parts of the body.

Dr. Theodore C. Janeway asked if there was any record to show how long before death the enlarged spleen had existed.

Dr. Biggs replied that both cases had been in the hospital only a few days, and no record on this point had been obtained. In both cases the enlargement of the spleen had been easily made out on physical examination.

Two Cases of Bacterial Infection of the Urinary Tract.—Drs. A. W. Williams and R. J. Wilson reported these cases, which, they stated, were chiefly interesting by reason of the fact that they illustrated very forcibly how bacteriological examinations might assist the surgeon in his work. The first case was one of kidney infection and one in which no positive diagnosis had ever been made until after the bacteriological examination of the urine, although several diagnosticians had suggested a number of probable causes that included everything from cancer of the kidney to tuberculosis. Briefly the clinical picture was one in which the patient was suffering from a mental disturbance, involving the loss of memory, at times so profound as to approach loss of reason. This was not a constant condition but was periodic, and it was noticed that the period of greatest disturbance occurred at the time that the urine of the patient was clear. This led to the bacteriological examination of the urine at a time when the patient was improved and the urine was very cloudy. The results of this bacteriological examination were as follows: The hanging drop showed many quiescent leucocytes and an immense number of non-motile bacteria; these latter were principally in the form of short bacilli with rounded ends, singly and in twos, with occasional short threads and coccus forms. Poured and streaked agar plates showed only two varieties, one greatly in the minority, from which was isolated the bacillus fluorescens liquefaciens (probably a contamination). The large majority of the colonies were composed of an organism having the following characteristics (in twenty-four-hour cultures): a short, thick, non-motile, pleomorphic bacillus with rounded ends, occurring singly and in twos, with occasional short threads and coccus forms; it was decolorized by Gram; in glucose broth at twenty-four hours there was marked polar staining; no spores were seen, in twenty-four hours there was abundant production of gas, and milk was firmly coagulated; gelatin was non-liquefied; there was growth along the entire stab, the surface growth was somewhat raised. On surface agar there was an abundant porcelain-like growth. The individual colonies had entire margins. On potato there was a yellowish-white abundant growth, with formation of gas. Three cubic centimetres of a twenty-four-hour broth culture inoculated into a guinea-pig intraperitoneally caused death in twenty-four hours. It would be seen that the characteristics of this organism corresponded very closely with those of the B. aerogenes as given by Flügge. It must be placed, therefore, in the coli communis group as a variety of that organism. The mental condition of the patient was now accounted for by toxæmia resulting from the poisons produced by the activity of the organisms retained in the pelvis of the kidney by occlusion of the ureter. When there was no communication between the bladder and the kidney, due to this occlusion, the urine would become clear and the mental symptoms become progressively worse until the flow of urine was again established, with consequent free and natural drainage into the bladder. After this natural drainage the mental symptoms would clear up until there was another stoppage of the ureter. This occlusion of the ureter, with the consequent symptoms, was occurring with such frequency that the advisability of draining the kidney by operation was considered. Here the surgeon was confronted by a condition that might well make him shrink from advising such an undertaking; in fact, all of the consultants did advise or suggest the expectant plan which in this instance simply meant waiting for the patient to die. These were the conditions: the patient, a lady seventy-three years old, was suffering from frequently recurring attacks of toxæmia, and as a result thereof was in a weakened and debilitated condition which made the prognosis a matter of days only (without the added shock of operation), and the possibility that after all the operation might not relieve the symptoms. It was no wonder that the surgeons hesitated. The operation was performed, the kidney drained from the outside, and the patient made a splendid and complete recovery. A few weeks after the operation they made cultures from the open sinus and the urine from the bladder as well, with a view to determine what organisms were present; the surgeon undoubtedly having in mind the advisability of allowing the sinus to close. The cultures were interesting from the fact that they showed the same organisms present in the urine and in the lower

end of the sinus, which communicated with the pelvis of the kidney, these being identical with the principal organism found in the previous examinations. The outer end of the sinus and the pus from the drainage tubes showed mixed infection in which the staphylococcus pyogenes aureus was predominant. The second case was that of a lady who suffered with considerable pain in the loins, had a slight elevation of temperature, and whose urine was somewhat cloudy and contained pus cells. The urine was collected under favorable conditions and sent to the laboratory for bacteriological examination; there it was found to contain several million bacteria for every cubic centimetre. In the poured agar plates two varieties were found in about equal numbers. One resembled that found in the first case, except that it possessed a moderate degree of motility; the other showed less abundant growth on all the culture media, the organisms were longer, more slender, showed polar staining, and were non-motile. In all other characteristics the latter resembled the first culture. They must, therefore, be classed as varieties of the bacillus coli communis. The diagnosis of infection of the pelvis of the kidney was made and operation arranged for. It was suggested that before operation the ureters be catheterized and the urine from them examined; when this was done it was found that the urine directly from the ureters was practically free from organisms, while that from the bladder showed the same number as before. From these examinations it was evident that the main infection was of the bladder. Operation on the kidney was given up and the bladder washed out with weak boric-acid-formalin solution and the patient made a good recovery.

Dr. W. H. Park said that he had been much interested in these two cases on account of the sharp contrast between them. In the former case the surgeon had been loath to operate until encouraged by the results of the bacteriological examination; in the second the surgeon had been on the eve of operating on the kidney when restrained by the bacteriological examination. The practical value of such examination was well emphasized in these cases.

Remarks on Some Uses of Paraffin in Bacteriological Work.—Dr. Park spoke on this subject. In the growth of tetanus and other anaerobic bacteria a layer of paraffin melting at 42° C. on top of the culture media had been found to give very good results. The growth of the bacteria and the development of toxins had been as rapid as under the usual methods. The very hot sterile melted paraffin could be poured on after the inoculation of the media, or inoculation could be made through the fluid paraffin, the culture media and paraffin having been sterilized together. The method seemed to be simple and effective. The paraffin could be readily separated from the glass by gentle pressure and the culture drawn off if desired.

A Further Report on the Action of Moderate and Intense Cold on Bacteria.—Dr. Park made this report. He said that the original report had been on the effect of cold on the typhoid bacilli in water. Twenty cultures had been frozen for varying lengths of time. On an average the cultures showed 42 per cent. of the bacilli living for half a week; 14 per cent. for one week; 7.5 per cent. for two weeks; 0.4 per cent. for three weeks; 0.1 per cent. for five weeks; .09 per cent. for seven weeks; .05 per cent. for nine weeks; .005 per cent. for twelve weeks; .002 per cent. for fifteen weeks; .0001 per cent. for eighteen weeks. At twenty-two weeks all of the bacilli in the twenty cultures were dead in the water. For the first three weeks all of the cultures were alive in the water. There was evidently quite a difference in the viability of the cultures. Experiments had also been made with the bacteria exposed to liquid air for different periods. At the end of three minutes only 18 per cent. of the typhoid bacilli were living; at the end of sixty minutes only 7 per cent. The colon bacillus acted very similarly. The hay bacillus with spores showed 55 per cent. living at the end of two hours. The streptococcus and diphtheria bacillus were tested for virulence after two hours, and this was found to be unaltered. Motile bacteria were found to be but little excluded from water in the act of freezing.

Tubal Abortion.—Dr. H. J. Boldt presented a specimen showing very well the process of tubal abortion. At the uterine extremity the tube was entirely occluded, while the abdominal extremity was well open. As a rule, the embryo was expelled in the course of a few days, but from the history in this case the process of expulsion had been going on for about three weeks. It was not common to have much hemorrhage from the vaginal route, yet in this case the hemorrhage had been so profuse that the clots were as large as in an ordinary intra-uterine abortion.

Spontaneous Diastasis of the Caput Femoris.—Dr. V. P. Gibney presented several specimens. The first one was of spontaneous diastasis of the caput femoris. Two days ago he had proceeded to excise the head of the femur in a child having a mid-dorsal Pott's disease and disease of the hip joint. The presence of a fluctuating tumor above the trochanter major had led him to attempt excision. On making the incision a little pus had been evacuated, and his finger had then felt the head lying loose in the acetabulum, and as sharply separated from the acetabulum as if it had been done with a saw or chisel. The acetabulum was perfectly smooth, but within the head of the bone was softened tissue which the pathologist thought to be tuberculous. He had seen only one other similar case, and in that one the head had been found lying in Scarpa's space.

Osteomyelitis of the Femur.—The second specimen was one of osteomyelitis of the femur. The child had developed the osteomyelitis about one year ago. Three months after admission it had been found that the left knee was apparently the seat of a phlegmonous inflammation. Two weeks later thick pus had been removed by aspiration. Finally an incision had been made on either side of the knee, and the pus evacuated. Two weeks later the incision had been enlarged. The tissue was found to be tuberculous. Since that time there had been no attempt at healing, and consequently a few days ago the thigh had been amputated. The centre of the bone had been found broken down and fetid. On sawing through the bone the epiphysis was found to have disappeared, and only the shell of bone remained. The pathologist had been unable to arrive at any conclusion regarding the etiology of the osteomyelitis or of the tuberculous process.

Tabes and Diabetes Mellitus.—J. Pal calls attention to the fact that, while great care is necessary to differentiate these two diseases owing to the frequency with which diabetes presents symptoms closely simulating early stages of spinal lesion, the two may also occur concomitantly in the same person, and cites a case in point. In this patient the gravity of the condition was increased by the development of pulmonary tuberculosis, which appeared to be the most active feature in causing death. At the autopsy a well-developed aortitis, supposably syphilitic in origin, was found, and the author thinks that this affords a clew to the combined clinical picture. The specific infection may be taken as standing in some causal relation to the tabes and the endarteritis, which latter in turn predisposed to the diabetes.—*Wiener klinische Rundschau*, January 6, 1901.

Therapeutic Hints.

Cystitis.—

℞ Spir. chloroformi ..... ʒ iij.
Tr. digitalis ..... ʒ iss.
Potass. acetat. ..... ʒ ss.
Infus. buchu ..... q.s. ad ʒ viij.
M. S. One or two tablespoonfuls t.i.d.

—Kelly.

To Hasten Expectoration in Catarrhal Pneumonia.—

℞ Potassii iodidi ..... ʒ i.
Tinct. opii camph. ..... ʒ i.
Spt. ammon ..... ʒ ss.
Syrupi ..... ʒ iv.
M. S. Teaspoonful a dose.

—Caillé.

Acne Due to Digestive Derangement.—

℞ Creosoti ..... ♏ ss.
Cerii oxalatis ..... gr. ij.
Pepsini pur. ..... gr. i.
Strychninæ sulph. ..... gr. $\frac{1}{60}$
Tr. belladonnæ ..... ♏ ij.
Podophyllotoxini ..... gr. $\frac{1}{10}$
M. et ft. capsula No. i. S. One such capsule to be taken after each meal and at bedtime, if needed.

Externally, apply:

℞ Acidi salicylici ..... gr. xx.
Ol. eucalypti ..... ♏ x.
Acidi borici ..... ʒ ss.
Ungt. zinci oxidi,
Ungt. aquæ rosæ ..... āā ʒ ss.
M. et ft. ungt.

—Shoemaker.

Tonsillitis.—

℞ Tr. guaiaci ammon.,
Tr. cinchonæ comp ..... āā ʒ vi.
Potass. chloratis ..... ʒ ij.
Mellis ..... ʒ vi.
Acaciæ ..... q.s.
Aquæ ..... q.s. ad ʒ iv.
M. S. A teaspoonful used as a gargle in a little water three or four times a day. Swallow a half-drachm or one drachm three times a day; children will swallow less.

—M. J. D. Dantzler.

Night Blindness.—Night blindness is the prominent symptom in retinitis pigmentosa, but in this form there is permanent narrowing of the field of vision and the ophthalmoscope shows the retinal pigment.—Halles.

Impetigo Contagiosa Bullosa.—When the disease is distributed over a large area and there is much crusting, a bland oil, such as carron oil, liquid albolene, or sweet oil, to which is added two per cent. of salicylic acid, should be used. This is rubbed well over the surface, the bullæ are opened, the crusts are gently detached, then the following powder is plentifully dusted on:

℞ Ac. salicylic ..... gr. xx.–ʒ ss.
Ac. boric. ..... ʒ ij.
Zinci ox. ..... ʒ ij.
Amyli. ..... ʒ ij.
M.

Baths are contraindicated. Ointments also seem irritating. A drying, mildly antiseptic, soothing dusting-powder, with a bland oil to soften the crusts and prevent the clumping of the powder when mixed with the serous oozing and contents of the bullæ, has been, with me, the most successful method of treatment.—Dr. Martin F. Engman, *St. Louis Medical Review*, November 10th.

Anthelmintic Enemata.—Thread worms and round worms are both met with in the rectum, the former more frequently. Their presence in children is not infrequently the cause of prolapse. Strong solutions of salt and water, or of quassia and water, will sometimes prove efficient. Or an enema composed of one to four drachms of spirits of turpentine mixed with the yolk of an egg, and added to four to eight ounces of water, may be given repeatedly until the worms are destroyed. Two drachms of asafœtida or aloes in water also answers equally well.—A. Ernest Mavlard.

Green Stools.—Stools can be considered green only when that condition is evident immediately upon their passage. They are due to a fermentation, which is doubtless the result of bacterial action. All stools become green a certain time after passage, caused by oxidation of the air.—Chapin.

Frequency of Perforation in Typhoid Ulceration.—In the case of children from two years to fifteen inclusive, out of twenty which were fatal in a total of two hundred and fifty-one cases of typhoid, six owed their death to perforation. In adults a similar number of investigations showed a mortality of forty-three, out of which eighteen died from perforation.—Hawkins.

Maggots in the Ear.—Until some more efficient germicide in fluid or powder form can be found which will eventually destroy the life of the larvæ and at the same time not be injurious to the tissues in which they are involved, we must rely on the application of the forceps or curette for their removal.—M. A. Goldstein.

Chronic Appendicitis.—Paul Klemm sums up the therapy of appendical disease as follows: (1) Acute catarrhal inflammation of the appendix is to be treated on conservative lines. (2) Operation is to be performed only in cases of urgent necessity. (3) After recovery from catarrhal appendicitis extirpation should follow in the free interval. (4) Operation is also indicated in those chronic cases in which there had been no acute attacks. (5) When a perforating form has been treated by operation but the appendix left behind, it is proper to wait for relapses before removing it, since atrophy often takes place. If relapses follow, extirpation is indicated.—*St. Petersburger medicinische Wochenschrift*, December 1, 1900.

Treatment of Retro-Displacements of the Uterus.—Edward McGuire states that uterine retrodisplacements may be treated in two ways, by mechanical means and by surgical operation. The method of the reposition of the uterus will depend on the complications present. If there are adhesions, massage should be employed. The sound and repositor are both dangerous instruments except in the most skilful hands. After replacement, the uterus may be retained by a well-fitting pessary—the Hodge, Smith, or Emmet will serve all purposes. A pessary is contraindicated in marked inflammation of the uterus and appendages, and when the uterus is held out of position by adhesions and cicatricial bands. The operations preferred by the writer are suspensio uteri and shortening of the round ligaments, generally the Alexander operation. The mortality should be *nil* or almost so in either, but there is less risk in the Alexander. The operation of suspensio uteri has the great advantage of permitting inspection of the condition of the peritoneal cavity. It is preferable when there is a decided prolapse, for it lifts the uterus on a higher level than Alexander's, and thereby fulfils a most important indication. In the occurrence of pregnancy a small per cent. of cases has been followed by abortions or difficult labor, which may endanger the woman's life.—*Virginia Medical Semi-Monthly*, December 21, 1900.

Medical Items.

A Poisonous Alkaloid in Potatoes.—Potatoes contain the alkaloid solanine, "although this is not generally recognized." New potatoes contain comparatively little of this poison unless they grow above the surface of the ground and have a green skin, when they are generally known to be poisonous. It is not, however, known generally that old potatoes contain much of this poisonous principle and that many cases of serious poisoning have occurred in late summer when old potatoes were used. In 1892 and 1893 there was almost wholesale poisoning among the troops of the German army. The symptoms were frontal headache, colic, diarrhœa, vomiting, weakness, and slight stupor, and in some cases dilatation of the pupils. Meyer investigated the matter and found in old potatoes kept in a damp place and beginning to sprout twenty-four times as much solanine as in new potatoes.—*Sanitary Home.*

Gas Cysts in the Brain.—The bacillus mucosus capsulatus, which is found in the nasal secretions of man in cases of influenza, has lately been recorded as the cause of air cysts of the brain and general gaseous emphysema in the case of a patient who died eight hours after admission to the hospital. At the autopsy it was shown that there was septicæmia with special localization of the micro-organisms in the brain. The results of the investigation in rabbits with the bacillus isolated from the organs of this case showed that general gaseous emphysema ensued. The patient on admission to the hospital was comatose, exhibited Cheyne-Stokes respiration, the apnœa lasting twenty seconds, the hands and feet were cold and cyanotic, and the skin was cool and moist. The patient died without recovering consciousness and was said to have been in the habit of taking large quantities of morphine. The interest of the case lies in the fact that it is not improbable that some of the published cases of gaseous emphysema in which no bacteriological investigation was carried out may have been caused by the bacillus mucosus capsulatus.—*Medical Press.*

Statistics of Insanity.—In a report on the insane patients of the Hudson River State Hospital Dr. C. W. Pilgrim of Poughkeepsie gives the following interesting statistics: of the patients admitted during the past year 41½ per cent. presented symptoms of melancholia, 32½ per cent. presented symptoms of mania, 20 per cent. were cases of dementia, and 6 per cent. had dementia paralytica. Among those admitted 30 per cent. recovered during the year or had prospects of recovery, 12 per cent. were improved, 11 per cent. died, and 47 per cent. were chronic patients who will probably die uncured. It is noticeable that 61 per cent. of the deaths during the year occurred during the months October to April and only 39 per cent. between April and October. Twenty-six per cent. of the deaths occurred between midnight and 6 A.M., 19 per cent. between 6 A.M. and noon, 31 per cent. between noon and 6 P.M., and 24 per cent. between 6 P.M. and midnight.—*The New York Sun.*

Vital Statistics of England.—In 1801 London contained not more than 922,000 inhabitants and the next largest place, Manchester, about 91,432. There were 112 towns outside London with populations descending from that figure to 4,000 and amounting in all to 1,400,762. The remaining towns distinguished in the table ranging so low as 1,000 inhabitants contained 774,253 inhabitants, and there were populous industrial areas containing 227,593 inhabitants, besides which portions of the areas surrounding towns but not actually parts thereof, were also populous. The bulk of the country, however, was thoroughly rural, say, over 34,000,000 acres inhabited by 4,721,252 persons out of a total population of 8,892,536. At this date 36 per cent. of the people lived in towns of 1,000 inhabitants and upward, but in 1891, 64 per cent. of the people lived in towns exceeding 4,000 in population.—*Public Health.*

Sunstroke: an Accident or a Disease?—In Railway Official and Employés' Accident Association *v.* Johnson, decided by the court of appeals of Kentucky in October, 1900, it was held that although an accident policy provides that it shall extend only to injury or death from "external, violent, and accidental means," and not to injuries or death caused or contributed to by disease, the company is liable for the full amount of the policy if insured dies from sunstroke received in the line of his duty as a railroad employé, when the policy also expressly provided that the company should be liable for only one-fourth of the amount of the policy if the disability or death of insured was caused or contributed to by sunstroke while not in the line of his duty as a railroader. This raises a very nice point, and the *New York Law Journal* disagrees with the verdict rendered, holding that sunstroke is a disease and not an accident. The journal in question quotes Longmore in support of this contention and goes on to say that in all its forms, ranging from "'heat syncope and 'heat apoplexy' to 'ardent thermic fever,' it is subjected to medical treatment as a disease. With what propriety for accuracy, therefore, can this malady be termed an accident any more than cholera, smallpox, or yellow fever or apoplexy? It may be an accident that a person is exposed to it, but the conditions under which the human system may be affected by it certainly belong to natural causes, which may reasonably be anticipated, as they come not by chance. The term 'accident,' as used in the policy, is presumed to be employed in its ordinary popular sense, which means 'happening by chance,' 'unexpectedly taking place,' 'not according to the usual course of things.' So that a result ordinarily, naturally flowing from the conduct of the party cannot be said to be accidental, even when he may not have foreseen the consequences." This reasoning is plausible, but it hardly covers the whole question. The popular conception of "sunstroke," that it is absolutely a "coup de soleil" and that it affects a person instantly like a lightning stroke, no longer has universal credence. Sambon is of the opinion that 'sunstroke," or siriasis, as he prefers to term it, is a disease, and that it is as often incurred in hot, badly ventilated rooms in tropical countries as under the direct influence of the sun. Nevertheless, the question is by no means wholly cleared up, and opinions differ as to whether the condition known as heat prostration is entirely identical with what is known as sunstroke. This much would appear a matter of common agreement, that in the tropics, at the time of the day when the sun's rays are the most intense, a person who has not his head, and especially the nape of his neck properly protected will, in the majority of instances, suffer from the condition denominated sunstroke.

Prehistoric Monsters.—For millions of years countless multitudes of living animals have played their little parts on earth and passed away, to be buried up in the oozy beds of old time or entombed with the leaves that sank in the waters of primeval lakes. The majority of these perished beyond all recovery, leaving not a trace behind, yet a vast number of fossilized remains have been in various ways preserved, sometimes almost as completely as if Dame Nature had

thoughtfully embalmed them for our instruction and delight. To geologists this stony record is legible, for the hieroglyphics are about as readable as those of the Egyptian monuments. A strange and wonderful earth drama is thus revealed. Shall we call it a tragedy or a comedy? Doubtless, tragic scenes occurred at times, as for instance when fierce monsters engaged one another in deadly combat. Backgrounds of scenery were not wanting. Then, as now, the surface of the earth was clothed in vegetation. Nor were the underground forces of the earth less active than they are now; volcanic eruptions often took place on a magnificent scale; volcanoes poured out fiery lava streams for leagues beneath their feet; great showers of ashes and fire dust were ejected into the air. Very little, indeed, is known about the causes of extinction; in some cases, as with the mammoth, the megatherium, or the moa, that great wingless bird of New Zealand, we can trace the hand of man as being the cause at work. But how about the dinosaurus, that remarkable order of reptiles now lost forever? Why have these died out while the lizards and crocodiles remain? Or why, again, have the winged reptiles (pterodactyls) disappeared? The most we can say at present is that these and many other orders now extinct seem to have been ousted or beaten in the struggle by types of a higher and more complex nature, and yet for all that many of the lower types remain. There must be some great law yet undiscovered. The plesiosaurus was a most strange marine monster. To the head of a lizard it united the teeth of a crocodile, a long neck like that of a serpent, the ribs of a chameleon, and the paddles of a whale. It was carnivorous and over twenty-two feet in length. The brontosaurus or "thunder lizard," so named on account of its size by the late Prof. O. C. Marsh, of America (who discovered this and scores of other new beasts), measured nearly sixty feet in length. Professor Marsh calculated that its live weight was about twenty tons. It will give the reader some idea of the size of this colossal monster when we say that in walking (or "making tracks," to use a colloquial expression) every track of the hind foot was one square yard in extent. Professor Marsh obtained casts of the brain cavity, which was but small, and therefore the beast was a stupid one. It was probably amphibious and vegetarian in diet. But larger still was the great atlantosaurus, a close relation. Unfortunately, not much about his skeleton is known, but this much we know, that a thigh bone measured six feet two inches in length. This can be verified at that vast treasure house—the Natural History Museum, London. Here in a case can be seen a cast of this very bone. The creature that owned it may have attained a length of over eighty feet, and must certainly have rather closely resembled the brontosaurus. The dinosaurus spread over a large part of the world, becoming very numerous and powerful.—*Pearson's Magazine.*

Acute Anterior Poliomyelitis among Adults on the Island of Guam.—Dr. Alfred G. Grunwell, assistant surgeon, describes in the "Report of the Surgeon-General of the United States Navy," some of the clinical features of this disease as witnessed by him when visiting the island of Guam, one of the Ladrones group. He says: "The onset of the disease was always very sudden, occasionally after a day or two of prodromes, with fever, and often with a chill; the fever lasting from three days to a week. The sensory symptoms were variable. In a few cases there was considerable pain, but in the vast majority, except some pain in the joints, there was no suffering. In a considerable proportion of the cases there was temporary anæsthesia, but in every case it soon vanished. In some instances the aching about the joints persisted for some time. The tactile sense and the heat sense in all observed cases were perfectly normal. There was no history of œdema in any case. In all the patients seen there was no weakness of the sphincters, and from all accounts of the acute stage of the epidemic the sphincters were unimpaired, except in two or three instances, when there was a very transient incontinence of urine which was troublesome. No case of impairment of the functions of any of the cranial nerves has been seen, and no psychical symptoms have been observed. It is stated, however, that in a few instances, in cases which died, loss of the power of speech was a symptom. There were no skin eruptions noted. In some instances a rigidity of the body, which developed with the fever, was described. This was probably orthotonos or opisthotonos, and was most likely due to accompanying meningitis, though this symptom was, from all accounts, by no means present in all cases. Headache as a symptom was variable, and was not emphasized by those who passed through the sickness. In some cases it was not present. The motor symptoms were the most interesting. In a certain proportion of the patients muscular twitchings were noted at the onset, and in some instances they persist, though they are at present very slight. Spasms of muscles or groups of muscles were entirely absent in many cases, and in those in which they were present they were probably identical with the above-mentioned rigidity. Paralysis, accompanied by flabby atrophy of the affected muscles, is now all that remains of the epidemic, and, so far as can be observed, the statement that every one who contracted the illness and escaped death was left with some member of his body paralyzed is borne out by facts. The paralysis is described as having come on suddenly, in some cases a week elapsing before it was fully developed. It was invariably accompanied by atrophy of the affected muscles, but there was a tendency toward later improvement. In some cases that have been under observation for three months the improvement has been marked. The paralysis is of muscular groups rather than of whole limbs, and in some cases the affected groups are so numerous and so widely distributed as to practically render the patient helpless. Ordinarily, however, the extensors of one arm or one leg or of an arm and leg are affected. In the arm the deltoid group, including the biceps and the brachialis anticus, is the one most commonly involved, though loss of power of the extensors of the forearm is often seen. In the leg the quadriceps extensor is almost invariably paralyzed and the tibialis anticus sometimes. Almost every patient examined has been able to flex the leg to a greater or less degree. The accompanying atrophy, which is invariably present, is often extreme. Unfortunately, there has been no opportunity for testing the electrical reactions of the affected muscles. The deep reflexes are invariably abolished in the affected limbs. There is a strong tendency toward improvement in the paralyzed limbs, but whether recovery will be complete in any one case it is as yet too soon to say. Again, just how much of the improvement is due to recovery of the paralyzed muscles, and how much is due to sound muscles gradually adapting themselves to some of the work of their unfortunate neighbors, is at present difficult to determine. . . . Occurring as it did at a time when epidemic cerebro-spinal meningitis was raging in so many different parts of the world, it might be well in conclusion to emphasize some of the reasons for regarding this epidemic as one of anterior poliomyelitis rather than one of cerebro-spinal meningitis. The features regarded as distinctive are as follows: The constancy and character of the paralyses and atrophy in those who took the disease and escaped death; the total absence of paralysis of any of the cranial nerves; the total absence of psychical symptoms; the absence

of petechial or other skin eruptions; the infrequency of orthotonos and opisthotonos; the comparative freedom from pain and the characteristic headache of meningitis; the complete abolition of the reflexes. Undoubtedly, meningitis was present in some cases, but in these instances it should rather be considered as a complication than the primary affection. The treatment, which has been extremely simple, has been directed solely to attempts to improve the condition of the paralyzed members, and necessarily so, since the disease in its acute stage had disappeared before the arrival of the expedition. Diet, massage, and prescribed exercise were found very useful. Large doses of the iodide of potassium were given in all cases, with strychnine and arsenic as adjuncts in some. There has been noticeable improvement in all the cases receiving treatment; in some of them the degree of improvement is gratifying."

Arsenic in Beer.—The alarming discovery was made recently in Manchester that much of the beer sold there contained arsenic in injurious quantities and that quite a large number of cases of peripheral neuritis were probably due to the consumption of beer. After a considerable amount of work the contamination was traced to a certain brand of glucose in the manufacture of which sulphuric acid made from iron pyrites containing traces of arsenic had presumably been used. The contamination was principally found in the vintage known as "fourpenny" and some of the samples contained arsenic in heavy amounts. As usual in such "scares" there have been probably many cases of "neuritis" reported in the production of which arsenic had no share whatever. In fact, the writer is inclined to the view from the result of analyses of a large number of samples of beer and from the examination of a fair number of suspected cases of arsenical neuritis, that whilst a substance of such dangerous possibilities as arsenic has no business at all in beer or any other article of food or drink, yet its part in the causation of neuritis is not so great as many would have us believe. The average amount present in twelve samples taken at the commencement of the scare was found to be about gr. $\frac{1}{40}$ per gallon of beer, the maximum being gr. $\frac{1}{19}$ and the minimum gr. $\frac{1}{100}$. The medicinal dose of arsenious acid is from gr. $\frac{1}{60}$ to $\frac{1}{12}$ given three times a day. Moreover, "arsenic is not an accumulative poison" but "is rapidly eliminated." These two things taken in conjunction make it necessary for medical men to exclude other and commoner causes of neuritis before putting the blame on any small quantity of arsenic which the beer may contain.—Dr. Meredith Young, *Medical Magazine.*

A New Method for the Sterilization of Sponges by Boiling.—C. A. Elsberg seeks to reintroduce the animal sponge into surgical technique by the elaboration of a simple yet reliable method of sterilization. The sponges are immersed for twenty-four hours in eight-per-cent. hydrochloric acid in order to remove all grit and coarser impurities, and then thoroughly rinsed in water. They are now boiled for from five to twenty minutes in an aqueous solution containing one per cent. of caustic potash and two per cent. of tannic acid, and again rinsed in sterile water, phenol, or bichloride solutions until all traces of the dark-brown tannin-potash mixture have been removed, and are to be preserved for use in two to five per cent. phenol solution. This process does not in any way impair the natural properties of the sponges which do not lose in softness, elasticity, or absorbing power, even on repeated boiling, while absolute sterility is insured. The potash mixture may be used indefinitely, the evaporated water being simply replaced as needed.—*Centralblatt für Chirurgie*, December 22, 1900.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended February 9, 1901:

		Cases.	Deaths.
Smallpox—United States.			
Florida, Jacksonville	January 26th to February 2d	1	
Illinois, Chicago	January 26th to February 2d	4	1

THE NECESSITY FOR A MORE CAREFUL INVESTIGATION AS TO THE CAUSE OF OUTBREAKS OF INFECTIOUS DISEASES.[1]

BY ALVAH H. DOTY, M.D.,

HEALTH OFFICER, PORT OF NEW YORK.

IN the advance made by sanitary science during the past quarter of a century, which has wrought many needed reforms in public sanitation, the urgent necessity for a more careful and scientific investigation as to the cause of outbreaks of infectious diseases has received but little consideration. This is to be regretted, as the prevention of this class of diseases is far more important than their treatment, although the latter has been exhaustively studied. The promptness with which an outbreak of infectious disease is brought under control or suppressed depends principally upon our knowledge of the means by which it is transmitted.

The treatment of infectious disease applies more particularly to the individual affected, whereas the prevention of the disease is of public concern. A full appreciation of this marks an efficient public health officer. It is my desire in presenting this to you to stimulate a careful and scientific inquiry into the subject.

In matters relating to the public health no belief has a stronger hold on the laity and many of the medical profession than that the clothing actually worn by well persons is a usual medium of infection, whereas careful investigation shows that this occurs only in rare instances. This theory or belief is a seductive one, inasmuch as it not only furnishes an easy explanation for the appearance of infectious disease, but also furnishes an excuse for not carrying out a rigid investigation to ascertain the true cause of the outbreak. I wish it distinctly understood that in presenting this matter I refer to the clothing worn by well persons and not the clothing or effects of those who are or have been suffering from infectious disease. Reliable evidence occasionally comes to us which tends to show that infectious diseases, more particularly smallpox and scarlet fever, are transmitted by the clothing of well persons. However, we have indisputable evidence that this is very uncommon. Physicians of large experience who have given this matter careful attention can cite but one or two cases in which it seemed proven to them that disease was transmitted in this manner. This alone is evidence against the theory referred to; for, if it were true that infectious diseases were frequently communicated in this manner, there would be abundant evidence of it. In a continuous experience of over twenty years in dealing with infectious disease, I have not yet met a case in which sufficient evidence was presented to show that the disease was transmitted by the clothing actually worn by well persons. During this period, however, I have investigated many cases in which infectious diseases were alleged to have been contracted in this way and in a large percentage of them conclusive evidence was secured to prove that the persons affected had been in contact with those sick with the same disease. This, I believe, is in full harmony with the experience of other practical sanitarians who have had ample opportunity to study this subject, and I feel convinced that we must look for other ways by which we can satisfactorily and scientifically explain outbreaks of infectious disease, the cause of which is in doubt. Experience teaches me that we will find this in mild, ambulant, or convalescent cases which are unrecognized as the carriers of infection. To ignore these and to assume that outbreaks of infectious disease are frequently due to the transmission of infection by the clothing worn by well persons means that we have not accepted the teaching of modern sanitation. Besides, it is dangerous because the real cause of the outbreak may remain unrecognized and continue to act as a serious menace to the public health. We have all seen cases of diphtheria, scarlet fever, smallpox, etc., which are extremely mild, so much so that the general health is apparently not involved. Such cases may enter a community unrecognized and when other cases appear as a result of this means of infection, it is commonly believed that the disease was transmitted by the clothing of well persons. It is under these conditions that this theory receives its strongest support. During the present outbreak of smallpox in New York City, many cases have been accidentally found which were extremely mild, so much so that a number of the persons affected were apparently well, performing their ordinary duties. One of them was recently removed to the hospital at North Brother Island affected with smallpox in a very mild form. The history of the case showed that the patient was a street-car conductor and had been at work while sick. Those who may have contracted the disease by exposure to this patient without knowing that he was suffering with smallpox would willingly believe that the infection came through the clothing worn by some well person with whom they were in contact. Scarlet fever and diphtheria may exist to all appearance as only a mild sore throat, or scarlet fever may not be recognized until desquamation takes place. Yellow fever and bubonic plague sometimes appear in such a benign form that they may pass unnoticed. Such cases are constantly being brought to the notice of health officials. Two cases of bubonic plague which were removed at this quarantine station from the steamship *J. W. Taylor* on November 18, 1899, were recognized only after the removal of the clothing of those on board and a glandular examination made in conformity with the rules and regulations of this department. It was then that the initial lesions and enlarged glands were found. Both patients, one of whom was the captain of the ship, reported well on the arrival of the vessel and apparently were so. This statement would have been confirmed by an ordinary examination; a subsequent outbreak of this disease in New York City or elsewhere, as a result of this exposure, would probably have been attributed to infected cargo or clothing. Those who are not constantly dealing with infectious diseases usually expect to meet typical cases and do not, as a rule, carefully consider the probable existence of mild or ambulant ones, which really constitute a greater menace to the

[1] Read before the Pan-American Medical Congress, Havana, February 7, 1901.

public health than those well marked, inasmuch as they frequently are not recognized or looked for. The belief that infectious disease is transmitted through the medum of the clothing of well persons in a way lulls a community into a false sense of security, inasmuch as it is not appreciated that a case of infectious disease may exist unrecognized in their midst. During the prevalence of the epidemic of typhus fever in New York City in 1893, a thorough and exhaustive investigation was made in each case brought to the notice of the health department; two of the most experienced inspectors being detailed for this purpose. The investigation frequently covered a period of a week or more, but in the great majority of the cases the most satisfactory and conclusive proof was obtained that the patient had been in contact with those sick of the same disease. Typhus fever also existed in New York during the previous year (1892). During the period just referred to (1892 and 1893), an epidemic of smallpox also prevailed in New York City. The total number of cases of each disease during this time (1892 and 1893) was as follows: typhus fever, 714; smallpox, 842. The division of contagious diseases of the New York City health department then consisted of 60 to 75 officers and employees, comprising diagnosticians, vaccinators, ambulance drivers, etc., all of whom were in more or less close contact with the patients or their apartments. They went frequently and freely to and from their homes and the seat of infection, and in no instance did these officers or men transmit typhus fever or smallpox to their families or friends, although fourteen of the employees were removed to the hospital with typhus fever, seven of whom died. It may be added that the employees were kept constantly under close inspection and were removed to the observation ward whenever they became ill; some were removed while on duty. The promptness with which this was done will presumably explain why their families were not infected. The observations of Murchison, Levy, and others who have had long experience with typhus fever, show that this disease is probably not infectious during its first period. On the other hand, however, the officers and men connected with the division of contagious diseases were generally in contact with cases which had not been properly diagnosed and were in an advanced stage of the disease. The statistics which I have just given relating to the subject before us are invaluable, inasmuch as I can find no account where epidemics of two such formidable and infectious diseases have existed at the same time and where such an unusual opportunity has been given to study how far the clothing of well persons may act as a medium of infection. May I ask if these results are to receive careful and proper consideration or are they to be laid aside because they conflict with existing theories which have not the endorsement of carefully collected statistics? The rigid investigation which was instituted by the New York City health department in 1893 in regard to the cause of infection, in each case of typhus fever discovered, was, I am sure, largely responsible for the suppression of the disease, and I am equally certain that typhus fever is more or less constantly present in some European cities to-day solely because similar investigation is not carried on.

If it were true that the clothing worn by well persons frequently acted as a medium of infection, then physicians in general practice would constitute a serious menace to the public health, inasmuch as they are constantly going from infectious diseases to other patients without change of clothing or disinfection. Health departments and public health officials would also deserve censure, inasmuch as members of families in which infectious disease exists are allowed to continue their daily duties in crowded shops and elsewhere and go freely in public conveyances, etc. There can be none of us simple enough to believe that the instruction of the family doctor that the well members of the family must keep away from the case is properly complied with. It is fair to assume that there is more or less communication with the patient, particularly when a nurse is not in attendance. It is true that the municipal health authorities do not allow the children of families in which infectious diseases exist to attend public schools; but as I have said before, other members of the family go and come whenever they please. Moreover, the disinfection which is performed after the termination of the case does not include the clothing worn by the well members of the family. When we consider this matter, it may be truthfully said that if the clothing of well persons is a menace to the public health, then the action on the part of physicians and public health officials regarding the prevention of infectious disease is something of a travesty. So far as I am aware, there are no statistics to show that infectious diseases are more commonly found in the families of physicians; furthermore, the appearance here of infectious disease is not by any means conclusive evidence that the clothing of the physicians has acted as a medium of infection, inasmuch as the members of a physician's family are subjected to the same exposure that others are. In recent years bacteriological research has rendered us valuable aid in the investigation of this matter. We now know that many pathogenic organisms can exist for a short time only in the presence of sunlight and fresh air, and we have good reason to believe that an exposure of but a few minutes inhibits the activity of many of the specific organisms to such an extent that they lose their power of propagating disease unless again placed in a favorable medium. Furthermore, it is probable that we have an exaggerated idea of the number of germs which attach themselves to the garments of those entering an apartment where infectious disease exists. What I have said regarding the clothing worn by well persons also applies to the cargoes of vessels, and we must look elsewhere for the means by which infectious diseases are brought to us from foreign ports. A careful investigation will prove that the medium of infection is almost always found to be actual cases of disease which may occur in a severe, mild, or convalescent form, and which frequently pass unrecognized. This at once calls our attention to the fact that passengers and crews coming from a presumably infected port are not, as a rule, subjected to a thorough exmination. We have gotten beyond the time when the statements of the passengers and crews or a perfunctory examination can be taken in lieu of a careful inspection. It is probable that in rare instances, or when some unusual circumstances exist, the ship's cargoes may act as a medium of infection. This, however, should not receive undue consideration in the construction of rules and regulations for the treatment of foreign vessels. Neither quarantine nor municipal health regulations can insure one hundred per cent. of protection without destroying commerce or business interests, and we are justified in enforcing only such rules and regulations as are dictated by practical experience and good judgment. For years it has been held that the cargoes of vessels coming from yellow-fever ports are a menace to the public health and are responsible for many outbreaks of yellow fever. It has also been stated that the clothing worn by well persons has likewise acted as a means of transmitting this disease. Now, after this view has been firmly impressed upon the public, we are presented with the result of the careful investigation made by Dr. Walter Reed, U. S. A., as to the means of infection in yellow fever. In reference to this matter, Dr. Reed does not hesitate to state in the most positive terms that neither the clothing

worn by well persons nor cargoes of vessels can transmit yellow fever. If this is true, and I feel satisfied that it is, what is to become of the definite statements made in the past, that cargoes and clothing of well persons transmit yellow fever—statements which, it is alleged, have been based on indisputable evidence? Everything in the way of the careful investigation of this subject tends to show that infectious diseases are almost always contracted by actual contact with or in the immediate vicinity of persons suffering with these diseases. This should be the keynote upon which we base our plans of operation as public health officers. By carrying this out it insures the careful and thorough investigation which is imperatively called for. Other means of infection, such as the clothing and effects of the sick and infected apartments, should receive careful consideration, and as I have already stated, in rare instances the clothing of well persons and cargoes of vessels may transmit disease—this also should be considered. Nevertheless, we should always keep prominently before us the fact that infectious diseases are generally contracted by being in contact with cases of a like character.

It has not yet been determined how long infected materials, such as the clothing of the sick, retain their power of transmitting disease. However, bacteriological investigation has taught us that, as a rule, it is for a comparatively brief time only and falls far short of the period usually accepted. In considering this subject we must again accept facts—for instance, the health department of New York City keeps under observation second-hand clothing stores. In almost all of these places families live in the rear of the store and are constantly in contact with the clothing, yet but little evidence has ever been presented to show that these people more than others are specially victims of infectious disease, nor are there reliable statistics to show that the rags which are used in commerce often act as a medium of infection. Egyptian rags, which are used largely in this country for the manufacture of paper, are really the cast-off garments of the natives of that country and, as may be inferred, represent about the worst form of this material. If rags constitute a means whereby infection is transmitted, those from Egypt would be a most potent source of danger. As the liability of rags to transmit infection has long been under discussion, and as this port is vitally interested in the matter, inasmuch as the bulk of foreign rags enters here, I visited Egypt in the fall of 1896 for the purpose of giving this matter a careful personal investigation. Through the courtesies of the sanitary authorities at Cairo and Alexandria, who are principally Englishmen, I was given access to the statistics relating to this subject and also conferred with the owners of warehouses where the rags are picked over and stored, and in no instance was I able to secure satisfactory evidence that infectious diseases were transmitted in this manner, although the rag pickers, consisting of women and children, are continuously exposed. The time that I refer to just succeeded the period when cholera occurred in Egypt and I was informed by the sanitary inspectors that many of the natives who died of this disease were found stripped of their clothing, which was hidden to prevent its confiscation by the health authorities in order that it could be sold to the ragmen who at certain intervals visit the different sections of lower Egypt. These observations are in accord with the information which I have been able to collect in the United States regarding this subject.

During the past two years considerable apprehension has been caused by the appearance, of bubonic plague at European and other ports. This has led to the fear that cargoes of vessels coming from these ports may transmit the disease. In considering the danger from this direction the fact has been lost sight of that during the past thirty years, while the plague has actively existed in the far East, both sailing-vessels and steamers from plague-infected ports, carrying all sorts of cargoes, consisting of wearing-apparel, food, etc., have been freely entering our ports without hindrance and discharging their cargoes without the slightest evidence that infection of any kind has been transmitted. With this experience and others of a similar kind before us, why should we now regard cargoes as a menace to the public health and impose restrictions which long experience has shown to be unnecessary? Again, recent experiments made by Klein, which consist of burying animals dead from inoculation of cultures of pest and other infectious diseases and afterward disinterring them at certain intervals, have shown that germs contained in the buried bodies lived but a short period: about twenty days. These facts should be carefully considered.

We are now entering upon a new era in the method of the prevention and treatment of infectious disease—an era which it is hoped will be dominated by the result of practical experience and scientific investigation. Theories which are not supported by facts must be put aside; unnecessary requirements, which, while they hamper business and commerce and add nothing to the public health, must be discontinued. We must appreciate that practical public sanitation cannot insure complete protection and that we are not justified in going beyond a certain point in the enforcement of rules and regulations for the protection of the public health. An attempt to carry into effect regulations which are neither reasonable nor necessary, and which are injurious to the business and commerce of the country, have frequently brought quarantine and municipal health ordinances into contempt, and have at times alienated the support and co-operation of the public.

Upon the discovery of a case of infectious disease it is the first and most important duty of a health official to ascertain if possible its origin. No investigation or inspection can be too rigid or far-reaching for this purpose. We should assume that the case under observation was contracted from some one sick with the same disease. If well-marked cases cannot be found we should look for mild, ambulant, or convalescent ones, and all who have been in contact with the case should be kept under careful observation. If the patient is from out of town his previous residence should be ascertained and the health authorities of that place communicated with. Such co-operation frequently leads to the most satisfactory results. A reform is also needed in the method of disinfection, which constitutes a most important means of preventing disease. This reform is needed on the part of both the family physician and the public health official. When a physician is called to a case of infectious disease, he should at once require that all of the clothing and effects of the patient be brought together; not one article should be missing. This material should be subjected to immediate and thorough disinfection; if for any reason this cannot be done at once it should be placed in the sick-room and treated at the termination of the case with the contents of the apartment. It is reasonable to assume that the patient was capable of transmitting infection before the character of the disease was known; besides, this procedure places the physician in the position of starting even with the case and to be reasonably certain that no infected material is stowed away to be brought out later. Under no circumstances should the disinfection at the termination of the case be left in the hands of the family. If the health authorities are not equipped to perform this work, then it should be done under the personal supervision of the attending physician. Modern investigation has left no excuse for superficial and imperfect work in this direction. We now

know that sulphur dioxide and formaldehyde gas cannot be depended upon for deep disinfection. Therefore, steam should be used for this purpose. It is to carry out scientific and modern disinfection that the health authorities of every city and town should be properly equipped and prepared to assume charge of all disinfection at the termination of cases of infectious diseases. Another most important means of preventing infectious disease is the prompt removal of the patient to a hospital set apart for this purpose. Any city or town which does not provide some adequate means for receiving and caring for infectious diseases is careless of the health of its people. It may be laid down as a law that a case of infectious disease cannot be properly quarantined in a dwelling-house or apartment; therefore, strictly quarantinable diseases, such as smallpox, typhus fever, plague, etc., should never be kept at home but should be removed to a building specially prepared for this purpose. If no permanent place exists, then a tent should be procured or a temporary structure erected where the patient can be isolated and kept under close observation.

In marine sanitation our effort must be to subject those coming from a presumably infected port to a most rigid examination. The statement of these people should be accepted only as corroborative evidence. Those who have had long experience in this matter know full well that even the most truthful will sometimes fail to give a satisfactory account of themselves when held in quarantine. Again, evidence of sickness is not always apparent. For the past three years I have required that all passengers and crews arriving on vessels from infected ports shall have their temperature taken before being released from quarantine. The result has shown this procedure to be of great value in the detection of mild cases, and it now constitutes a part of the regular inspection. Many cases of yellow fever and other infectious diseases have been detected in this manner. It is the practice of this department to hold for observation all persons whose temperature is 100° or over. The use of the thermometers many thousand times at this station has shown that temperature of 99° or 99½° are found in persons who are perfectly well, a temperature also of 100° is not uncommonly found in well persons and may be due to slight causes and often disappears in a few hours. Death in transit on ships arriving from infected ports without surgeons should be considered at least suspicious and treated accordingly. The captain is not competent to make a reliable diagnosis and it must always be remembered that he is anxious to reach his destination. Even if a surgeon is on board a most careful and thorough investigation should be made regarding death at sea, and in all instances the benefit of the doubt given to the public.

In conclusion, I desire to say that it has been my effort for a number of years past to give the subject of the prevention of infectious disease most careful and thorough investigation. The conclusion which I have arrived at, and present to-day, represents the result of this work. I am satisfied that the clothing of well persons and the cargoes of ships are rarely the means of transmitting disease. This statement gives no license to omit reasonable precautions to prevent the possible danger from this source; but, on the other hand, is intended to call attention to the urgent necessity of looking elsewhere for the cause of an outbreak of infectious disease the origin of which is unknown. I believe this to be mild, ambulant, or convalescent cases which pass unrecognized. An acceptance of this view certainly does not mean that we should relax our efforts to protect the public health, but tends to bring about a more careful and thorough investigation as to the means of transmission of infection, which I believe is imperatively called for.

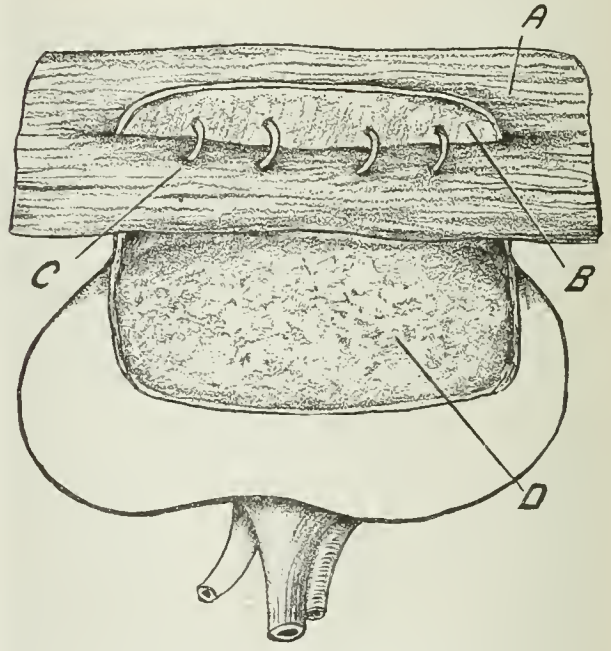
A METHOD OF FIXATION FOR LOOSE KIDNEYS.[1]

By ROBERT T. MORRIS, M.D.,
NEW YORK

When Hahn, in 1881, first performed nephropexy he thought it sufficient to pass sutures through the fatty capsule of the kidney alone, but later he found it necessary to pass them through the fibrous capsule, and in his first report of twenty-seven cases he reported fifteen cures, four improvements, seven failures, and one death—a most unsatisfactory proportion of good results as compared with later-day experiences.

Hahn and others then carried sutures farther and through the parenchyma of the kidney, but with little better results.

Guyon first suggested the removal of part of the fibrous capsule of the kidney, believing that the lymph exudate from bare parenchyma would make a firm connective-tissue anchorage for the sutured kidney. This idea with various modifications has given most excellent results at the hands of some operators and



A. Psoas or quadratus muscle; *B*, flap of fibrous capsule; *C*, sutures; *D*, bare parenchyma.

not wholly satisfactory results with other operators. Some have removed the fatty capsule almost completely and very little of the fibrous capsule; others have removed almost all of the fibrous capsule and little of the fatty capsule; some have sutured the kidney in its normal site; others have drawn it well up into the muscle incision in the abdomen and have fastened it there; others have sutured it lower than its normal position, believing, and very correctly, that it is not the position of the kidney but the influence of its excursions that causes trouble.

Edebohls has given us what appears to be a very satisfactory operation of a class in which the parenchyma of the kidney is exposed and sutures are passed through the parenchyma, but I have a feeling that we do not all know the final result of our operations as far as the perfect comfort of the patient is concerned. The patient who has been relieved from grave distress may still have persistent local pain and tenderness, which leads the family physician to believe that the operations for floating kidney are not so satisfactory as we surgeons count upon them to be.

Senn made a radically different procedure in re-

[1] A paper read before the Section on Surgery of the New York Academy of Medicine, December 10, 1900.

moving the fatty capsule, scarifying the fibrous capsule, and then packing iodoform gauze about the kidney until granulation tissue was well formed. The gauze being removed, secondary adhesions occurred and gave a firm fibrous anchorage for the kidney. I have tried Senn's method in only two cases and had a very pretty result in both these cases, but the time required for repair was altogether too long and the scar remains too strongly in evidence. In cases in which we can suture for primary union, the scar may be hardly discernible a few months after operation. The chief advantage and intention of Senn's operation were to avoid the passing of sutures through the parenchyma of the kidney.

There is no doubt that scar tissue with fibrous replacement of a considerable part of the parenchyma does occur in some cases, as I have had occasion to observe when patients later were subjected to operation for some other trouble, or when post-mortem examinations were made years after operation.

About two years ago in reading over some foreign journals at the Academy library I found mention of a method for fastening the loose kidney by turning up a flap of the fibrous capsule and drawing it through a slit in the psoas muscle. I made a note of the method at the time without keeping the name of the author in mind, and since that time have been unable to find it. I have received letters from several physicians asking about my operation, as this is the one that I have performed in all my cases for the last two years, but I wish to state that I have no claim upon the operation except that it was adopted as one that seemed rational, and that up to the present time it seems to me to be the most desirable one.

In this operation a flap of capsule including the larger part of the mesial surface of the kidney is incised with a scalpel and the flap of capsule then stripped up from the parenchyma but remaining attached at the convex border of the kidney. The flap of capsule is drawn through a slit in the psoas muscle or in the quadratus muscle, indifferently as one chooses, and is there sutured in place. This brings bare parenchyma also in contact with the psoas or quadratus fascia, where it forms a firm connective-tissue attachment. The operation certainly avoids the necessity for passing sutures through the parenchyma of the kidney and I have had no reports of recurrence of loose kidney up to the present time. It is not possible to keep track of all of one's cases and in writing to forty or fifty patients for post-operative reports several letters are required on an average for each patient, so that it gets to be quite a serious matter, but all patients or their physicians have been asked at the time of the operation to report any recurrence.

In connection with this description of an operative method I wish to present some incidental notes briefly on the subject of loose kidney.

The frequency of occurrence of loose kidney will never be determined until we have some standard for comparison. One author, for instance, says that ten per cent. of all women who have borne children have this complication; another author tells us that twenty per cent. suffer, while a prominent pathologist, who is largely engaged in post-mortem work, recently informed me that he did not believe much in this matter of loose kidneys because he did not often find them in his post-mortem work.

As a matter of fact, loose kidneys are so common that every general practitioner presumably has a number of patients who are suffering from this cause, and the reason that more cases are not discovered in post-mortem examinations is that the kidney promptly assumes its normal position, usually while the patient is in a recumbent position, and rigor mortis fixes it quite securely in place. The cases seem to be almost as common as cases of eye-strain at sanatoriums where neurasthenics gather.

Clinically our cases can be grouped into three chief divisions: first, those of loose kidney without troublesome complications; second, cases with distressing complications; and third, cases occurring as a part of a general enteroptosis in which the kidney plays only a part.

Cases of the first sort are well represented by a young lady patient of mine, in perfect health, who rides across country to the hounds and who came to the office to find out what the "two funny little round things" were in her abdomen that appeared after any particularly hard ride. Both kidneys were very loose, but were producing no symptoms apparently. I presume that in her case the condition was congenital, that the kidneys were supplied with mesonephron and the viscera had become accustomed from childhood to the presence of the floating kidneys.

Cases of the second class suffer from three entirely separate kinds of symptoms: those due to direct pressure upon the bile duct, those of pressure upon the duodenum, and those of pressure upon the superior mesenteric vein.

I have seen several patients in consultation who were believed to have gall stones and who suffered from jaundice, but in whom loose kidney was found to be the cause of obstructive jaundice. Cases of direct pressure upon the duodenum are common enough. The duodenum cannot get out of the way because of its lack of a mesentery, and the interference at the duodenum gives rise to stomach disturbances of various degrees. In one of my cases it had resulted in such a dilatation of the stomach that the latter when distended reached to the hypogastric region, and I was obliged, in addition to fixing the kidney, to do a gastrorrhaphy, taking up most of the stomach in a large longitudinally sutured fold. The patient made an excellent recovery.

I have seen a number of cases that are not generally recognized by the profession but that have been well described by Edebohls, with symptoms due to pressure of the loose kidney upon the superior mesenteric vein, causing venous stasis and congestion in the region of the appendix and cæcum. These cases were sent to me usually for operation upon the appendix, but a loose kidney was found to be the cause of the chronic congestion.

While the direct pressure complications are common enough, reflex disturbances are still more common because of the extensive sympathetic connection between the kidney and the semilunar ganglia. Reflex disturbances of this sort are most common perhaps in the stomach, but in one of my cases the chief demonstration was in spasm of the œsophagus. The patient, an actor, had been seen by surgeons in New Orleans, Cincinnati, Philadelphia, and Boston, who had proposed various œsophageal operations. The poor fellow was so thin that the excursions of his loose kidney could be readily observed on inspection with each inspiration and he was barely able to go on with his work, living upon a skimmed-milk diet. He wished to complete an engagement before submitting to operation and I instructed him to hold his kidney in place with his hand and assume a recumbent position while eating a meal, and to remain in the recumbent position until digestion was under way. I heard from him about two months later, saying that under this treatment he had gained nearly thirty pounds in weight and was so well that he did not wish to have any operation done. I presume that the fatty capsule of the kidney had regained such a large amount of adipose tissue that the kidney ceased its extensive wanderings.

In the reflex class of disturbances we often have

symptoms referable to the heart, or pain reflected to the leg, or functional neurosis of the intestine due to disturbance of Auerbach's plexus or Meissner's plexus.

At a meeting of the Medical Section of the academy last spring, when membranous colitis was the subject for discussion, I was much surprised at the opposition met by one speaker who stated that mucous or membranous colitis cases represented a functional neurosis. I stated on that occasion that most of the cases of this sort that came to me were cases dependent upon loose kidney. Whether the loose kidney cases of membranous colitis form any important proportion of the entire number, I could not say, but simply that they formed a good proportion of the ones that came to me as a surgeon.

Shortly after this meeting, a physician, Dr. H. T. R., twenty-nine years of age, came to my office with a typical case of membranous colitis, and I asked him to give me a careful note of his symptoms before and after operation for loose kidney. His letter, under date of November 27th, gives me the following comparison. "Before operation after a walk of fifteen minutes I would be completely tired out and bowel cramps would begin. There was constant pain in the back and right side of the abdomen. I would awake every morning with colic lasting about thirty minutes, and this would end with a passage of mucus and membranous casts. I felt exhausted and mentally depressed all the time. Appetite capricious, and distress after eating. I felt that my professional work was about at an end. Present condition—I can walk all day without tiring; there has been a gain of more than ten pounds in weight; appetite fine, no distress after eating. No more mucus or casts from the bowel; the movement is apt to be lumpy at first, but otherwise normal. I feel refreshed and rested in the morning, cheerful, never depressed, and very happy over the result of the operation." Now if this is not a case in which the membranous colitis was a functional neurosis and dependent upon the loose kidney, I am at a loss to know how to classify the case. It is so similar to other cases in my experience that it would not have caused comment or even this report had I not happened to be present at the meeting of the Medical Section last spring.

The third division of loose kidney cases occur as a feature of a general enteroptosis, and operation for loose kidney is in itself not likely to be of much consequence unless we shorten the falciform ligament of the liver and the gastro-hepatic omentum at the same time. These cases need long-continued treatment by static electricity, abdominal massage, the alternate douche, and other treatment which requires the patient to be in pretty good circumstances in order to carry the case to a successful termination.

The cases of general enteroptosis, however, are very satisfactorily treated without any operation whatever in a fair proportion of the cases. The majority of cases of loose kidney perhaps, in my practice, are not subjected to operation.

Cases for operation, according to my belief, are the ones which continue to produce important symptoms after the diagnosis has been well made and abdominal support and general medical treatment have been well tried.

The method of examination that I commonly use is that described by Israel. A line is drawn parallel to the middle line of the abdomen, distant from the middle line of the abdomen as far as the point in the middle of Poupart's ligament and extending to the costal border.

In examining the right kidney the fingers of the right hand are placed on the upper extremity of this line, the left hand at the same time lifts the quadratus lumborum muscle. The fingers of the right hand are depressed more and more with each expiration of the patient until the lower pole of the kidney can be felt or at least approximated. The patient is then asked to take a deep inspiration, when the kidney, if loose, will slip out beneath the examiner's fingers very distinctly and can often be carried to a point below the navel. The loose kidney commonly falls into its normal position with the patient in a recumbent position, but often is discovered at some other point in its line of excursion. Other methods of examination I will not discuss here, as my intention has been to present only brief points on the general subject, in order to bring out certain salient ones for discussion.

8 West Fifty-sixth Street.

CONVULSIONS WITH SCARLET FEVER, AND THE REPORT OF A VERY SEVERE CASE WITH PERFECT RECOVERY, AND IMPORTANT DEDUCTIONS FROM THE TREATMENT.

By HERMAN E. HAYD, M.D., M.R.C.S. Eng.,

BUFFALO, N. Y.

Of all the complications of scarlet fever, none are more important and none are associated with more danger and have graver responsibilities than convulsions. They occur in all kinds of epidemics, whether the disease be mild or severe, whether the eruption be intense or moderate, and occasionally when it is so slight that the disease was not even suspected. Sometimes they are seen before any rash appears—in fact, the little patient is simply overwhelmed by the intensity of the poison, and the urinary suppression and convulsions are but the evidence of the intense general systemic infection. Usually they are seen at the end of the second week or the commencement of the third, when the desquamating process is fairly well advanced and the patient is well on the road to recovery. Occasionally they manifest themselves without any premonitions, when the urine is being passed freely, and of good color, and of good specific gravity, and when the patient is begging for food, and is to all intent and purpose seemingly well. They are to be feared, therefore, at all times and under all conditions, until the patient is far on to convalescence. Their approach may be sometimes anticipated by certain nervous phenomena, such as irritability of temper, restlessness, transient headaches, occasional twitchings of the muscles of the face and hands, slightly disturbed sleep, petulance upon awakening, capricious appetite, or anorexia, or vomiting, etc. The urine may be practically normal, reduced in amount simply a few ounces, of normal specific gravity, and with a small diminution of solids and urea. Perhaps a minute trace of albumin may be found, and a hyaline cast, with an occasional red blood cell. Such slight evidences of disturbance may exist for days, and make little impression upon the attendant or nurse, or only for a few hours, when a terrific explosion may take place in one or more convulsions, which may come to a fatal termination, or the little patient may remain dangerously ill for weeks or even months, and have repeated returns of the convulsions upon the slightest provocation; or these slight warnings may pass away in a few days and the patient rapidly get well.

The initial and objective signs of the nephritis, which is undoubtedly in most cases the cause of the convulsions, are slight puffiness of the eyelids and pallor of the face. These, together with faint pitting of the extremities and fulness about the ankles, may be present for days, and pass away without any further developments; or they may increase to a general dropsy, and still no convulsive seizures may occur; or

they may suddenly and without warning, while the urinary tests are satisfactory, be accompanied with one or more convulsions, and, if not fatal, are followed by a general anasarca and marked albuminuria with blood and epithelial casts in abundance. Often the urinary examination does not stand in any proportion or relationship to the condition of the patient, because we frequently see marked dropsy and accumulations of fluid in all the hollow cavities, and the urine loaded with albumin, casts, blood, and urates, and yet see no complicating convulsion; in fact, it has been my experience not to find marked urinary evidences in many cases of convulsions until the convulsion has occurred. Moreover, I believe that in many of these cases there is at first no serious kidney lesion, and that the condition might better be termed a renal insufficiency or functional inactivity, due perhaps to a paralysis of the secreting cells of the kidney tubuli, because the chemistry of the urine is not commensurate with the symptomatology. This inactivity of function is further increased by auto-infection and auto-intoxication, the result of putrefactive changes in the stomach and bowels, because these patients often in a few hours after the ingestion of certain foods have a convulsion or show convulsive twitchings of the muscles of the face and extremities, which irritability remains until such poisonous products are eliminated or their energy is spent. Some peculiarity or impressionability on the part of the subject must exist to make this complication possible, because some of these patients had been voiding in the twenty-four hours three or four pints of urine, with a specific gravity of over 1.015, and yet have convulsions.

We know that the poison of scarlet fever expends its special energy upon the brain and spinal system, and these organs suffer quickly, frequently, and seriously in many epidemics.

Again, the lymphatic and glandular apparatus is more often involved, while in other persons the poison shows its special predilection for the kidneys and lungs.

What is responsible for these peculiar phenomena in the one case and not in the other, we cannot say. Nor do we know what this vulnerability of tissue is, nor are we prepared to deny that certain toxins are developed in certain individuals in certain epidemics of specific diseases which spend their energy upon certain organs peculiarly predisposed to their irritating action. Why one person in good health, with excellent family history, and with the most careful and vigilant nursing, should have one complication and escape all others can then in a measure be understood. Many cases of convulsions are no doubt due to carelessness in nursing; to improper food, both as to amount and quality; to want of care and attention of the skin during the desquamating period; to colds, etc.

Mild cases of scarlet fever are often the subjects of nephritis and convulsions. I have been frequently called to a case of dropsy and convulsions, and upon careful inquiry it was made out that the child some weeks previous had been slightly sick, and that scarlet fever existed about that time, either in other members of the family or in the immediate neighborhood. Scarlet fever, however, was not diagnosed in that child, and the illness being so slight, the child was at once permitted to be out, perhaps in inclement weather, or after a romping, vigorous play, sat down in a draught and took cold. An acute congestion of the kidneys, or perhaps a nephritis with convulsions resulted. This class of cases is not rare, and is easily accounted for. The poison of the scarlet fever, although attenuated, left its impress upon the kidneys, and the sudden chilling of the cutaneous surface rapidly brought an influx of blood to these already sensitive organs.

Another class, which is, however, of greater clinical interest and importance, comprises those due to gastric and intestinal toxæmia. I am strongly of the opinion that there is a class of convulsions seen in scarlet fever, as well as in pregnancy, which are the result of toxic elements generated in the gastro-intestinal canal, and these toxic elements are absorbed, and exercise an inhibitory influence on renal secretion. This conviction is borne out by the experience of the case I purpose to report in this paper, as the relationship of cause and effect was seen so often and with such terrible consequences by the attending physician and nurses. Convulsions occurred when the patient was passing per diem as much as three pints of urine, of a specific gravity of 1.012 to 1.018 and of fair color, but containing only six to eight and twelve grams of urea in twenty-four hours. Specific gravity, therefore, gave but little indication (in fact, none) of the toxicity of the retained elements which caused the convulsive outbreak; in other words, mere specific gravity in itself, as represented by the index of the urinometer, is no safe guide for renal secretion. Other products can exist in urine, which are capable of making a fairly dense specific gravity, such as the chlorides, the sulphates, the alkaline and earthy phosphates, and the indoxil compounds, and still the economy can be retaining toxic elements capable of making a convulsion.

What the poison is that makes convulsions is still a debated problem—whether it be retained urea or some subtle derivative of the urea compounds, future chemistry will have to verify. One thing, however, seems reasonably certain, that *pari passu* with a diminished excretion of urea a proportionate nervous excitability results with perhaps a convulsive explosion. Repeated urea analysis, therefore, is of the greatest importance in conducting any case of scarlet fever. Daily urea calculations, or even calculations as often as every second and third hour night and day, or after the ingestion of any food or nourishment, may become necessary and of the most vital importance for the proper conduct of a serious case of scarlatinal convulsions, because by this vigilance only can we determine whether certain articles of food are not contributing to the lessened excretion of urea and its compounds and their retention in the system.

If we accept the theory that convulsions are often the result of putrefactive changes of certain food products in the bowels, then the question of the nourishment of the patient becomes a very important one. I am satisfied that too much anxiety exists in our minds, and particularly the lay mind, as to the necessity of food in the acute infectious diseases, and particularly those in which kidney complications are possibly frequent concomitants or complications of the disease. Tanner, the world-renowned faster, was more than a mere dime-museum freak who appeased and satisfied the curiosity monger. His fasting demonstrated a great physiological truth, that for weeks a person can exist without extraneous food, with a liberal supply of water, and that he can be fairly well sustained for days by his own stored-up food-generating and fuel-producing energy. That being a demonstrated fact, I maintain that food and nourishment are not matters of vital importance until emaciation and weakness prove their necessity. Sometimes the articles of our simplest diet lists are potent agents in the generation of intestinal putrefaction, and perhaps are the last straw that breaks down the weak and imperfectly functionating kidney. Although farinaceous foods, as rice and sago, are ordinarily permitted in the diet of these febrile patients, I am positive that they sometimes and perhaps often bring with them a mortality. Milk is the food *par excellence*, because it leaves but little waste and residue products in the bowels; but when it is not

borne, either from peculiar, idiosyncrasy or indifference or spleen or disgust for it, nothing should be given by the mouth, and the patient should be sustained, if necessary, as well as possible by nutrient enemata, because the dangers in these trying cases are infinitely greater from intestinal toxins than from starvation, and the index of that toxæmia is a relatively diminished excretion of urea and a proportionate increase of indican and its correlatives.

With my own little patient, we were driven to the point of starvation by the terrible exigencies of the case, and we realized, after three different attacks of convulsions, that food simply consisting of chicken broth thickened with a little rice or sago brought in its trail invariably a lessened excretion of urea and an increased amount of indoxin, and with these chemical data, clinical evidences in the shape of twitchings of the muscles of the face and neck, frontal headache, and often very pronounced irritability of temper and restlessness, which ended in two and five and seven convulsions. For ten days even a little patient, exhausted by many weeks of sickness and from the first day of that illness under a most restricted diet, got nothing by the mouth excepting water and such small additions of brandy as were thought advisable, and finally, when but a living skeleton and on the brink of dissolution, as a last resort, after many sessions of anxious debate between the medical men and a very intelligent father and mother, milk three times diluted with water was again tried. It was borne now, and it was cautiously increased in strength, and in four days thirty ounces of milk, diluted in various proportions of water, were taken in twenty-four hours. In the early part of the illness, milk in any possible combination was not tolerated, not alone because the stomach rejected it, but because our otherwise obedient and dutiful patient would not take it. No bribe was great enough or persuasion powerful enough to overcome her natural aversion for milk. The stomach and bowel rest which followed as a natural consequence upon rectal alimentation only, and the gradually increasing kidney strength because no extra work was thrown upon them by reason of auto-infection from stomach and bowel fermentation, enabled her to take the diluted milk, which soon satisfied the thirst and desire for food and nourishment. The kidneys had rehabilitated themselves, and in three days the amount of urea had increased from ninety grains per diem to two hundred grains, and finally got as high as six hundred and thirty grains in twenty-four hours. Indicanuria, which was evidenced by a very dark purple reaction—in fact, as dark as port wine—practically disappeared, and the urine very soon showed simply traces of albumin. Strength rapidly came, and a surprisingly quick convalescence; in fact, in a few weeks the patient was well on to recovery. Milk and junket and various combinations of milk and somatose were taken with avidity and relish, and apparently without any waste. Everything was absorbed, properly digested, and oxidized, as was evidenced by the alvine evacuations and oft-repeated chemical and microscopical urinary examinations.

And now let me give you the history of the case more in detail, the treatment employed, and the practical deductions which resulted from a close observation of constant daily attendance for sixteen weeks, seven of which were practically devoted to her case alone.

H. M——, aged ten and one-half years; always a strong, healthy child, but not of rugged build. She never suffered from convulsions during dentition, or during an attack of measles, mumps, or chicken-pox; in fact, she never had a complication or sickness of any serious importance in her lifetime. She never was a croupy child, like her brothers, and was blessed with splendid digestive organs. She is of nervous organization, quick and impetuous, and with an exceptionally bright mind and intellect, and with a nature full of play and spirits.

On March 12, 1900, she developed scarlet fever. It was an average case, much less severe than her brother's, who was ill at the same time. The temperature never ran above 101.5° to 102° F., the rash came out nicely, and there was little associated sore throat. Instead of the temperature falling to normal after the eighth or tenth day or thereabout, she continued to have a little fever at night, say 99.5° to 100° F., and the pulse would range from 96 to 110. The stomach was weak; there was an indifference and dislike for nourishment, but she would take a fair amount of broths and milk by persuasion, and a little rice and bread and butter. No solid food was administered, excepting once a very small piece of chicken, and again a piece of fish or sweetbread. She was kept in bed continuously, and only once sat up for a short time and walked into her brother's bedroom. The urine was passed in full amount, three pints in twenty-four hours, with no albumin and no casts, and two hundred and twenty-six grains of urea, and again two hundred and fifty-six grains were eliminated. The skin was bathed regularly and anointed twice daily with vaseline. About the fourteenth day the face and forehead were noticeably pale, and the skin seemed slightly thickened, although there was no pitting of the extremities or puffiness of the eyelids. The bowels were kept soluble, and Basham's tonic diuretic mixture was administered three times daily. On the sixteenth day a little puffiness of the eyelids was seen when she awoke in the morning, and the stomach was a little more intolerant of food; there were nausea and a sense of fulness and distress after eating. This condition continued with a little increase of the puffiness of the eyelids and a little about the ankles, and the urine began to fall in amount, say to thirty ounces; the specific gravity was 1.021, and there was a slight trace of albumin. The urine was carefully examined every day, not alone at the patient's bedside, but samples were taken to the hospital and centrifugalized. No casts were found, and other than an occasional red blood cell and renal cell the urine contained nothing of importance; the albumin even disappeared, or at all events diminished to the smallest trace discernible by different tests.

A vapor bath was given on the afternoon of the twenty-second day, although the skin was soft and moist, more as an experiment to get rid of the puffiness of the face, and to give the little patient an idea how a bath felt in case a stronger necessity came for its employment. The patient for the first time was very restless that night and did not sleep well, and at eight o'clock on the following morning, April 4th, I was called by telephone, because she was in convulsions. I hurried to the house, and immediately dropped a few grains of calomel upon the tongue and began the administration of chloroform. Dr. Hopkins was sent for, and he joined me throughout the future progress of the case, and later Dr. Carpenter, who made frequent urinary examinations. Only two pronounced convulsions occurred, but it was evident that the patient was very much poisoned, because the head would be jerked over to the right side, and the eyes would be rigidly fixed with a pronounced external strabismus just as often as the anæsthesia was lessened; urinary suppression was nearly complete, because several hours after the convulsion, no urine being passed, a catheter was introduced into the bladder, but only an ounce and a half of urine was obtained. The back was dry-cupped, and poultices were applied over the lumbar region, and finally two pints of water were introduced under the skin into the

cellular tissues through four different points. Quiet and sleep were further induced by chloral gr. v., and antipyrin gr. v., injected per rectum every fourth hour, after having first washed out the bowels with a copious injection of several quarts of water through a long rectal tube. Strychnine gr. $\frac{1}{60}$, and digitalin gr. $\frac{1}{100}$, were also given every fourth hour hypodermically. The temperature ran very high, 103° to 104° F., and pulse 116 to 140, and respirations 34 to 52. She was now very much bloated, and a condition of general anasarca existed. She was sponged freely, but no effect was noticeable upon temperature and pulse, and finally cold packs were employed from 64° to 80° F., the first being 64°, with a very happy result. Tincture digitalis ℥xii. was also added to the chloral and antipyrin injection, and continued as before every fourth hour. The large bowel washes were given every sixth hour for a few days, and the temperature of the water was reduced to 78° and 80° F., which also brought down the fever, produced quiet and restful sleep, and cleaned out the bowels of any fermenting materials. During the second twenty-four hours, sixteen and one-half ounces of urine were passed, and one sample was lost. It was loaded with albumin, urates, and epithelial and blood casts and blood cells, and renal and bladder epithelium. Salines were administered, and the bowels moved four or five times, and on the third day fourteen ounces of urine were passed, and three samples lost. The stomach was quiet; the nausea and vomiting, which had been distressing, were better, so that water could be freely given, and some chicken broth. Nutrient enemata, consisting of peptonized milk ℥iii., with somatose ʒi., were given every fourth hour, often combined with medicines, and fifteen minutes after the chloral and antipyrin injections, which had the effect of quieting any bowel irritability.

On the 7th of April, the third day after the convulsion, she rebelled against the broth, so a little rice was added to it, more to give flavor than for any nutritive value, as so little was used. The afternoon temperature was 99.5° to 101° F. and the pulse 116 to 124; sixteen ounces of urine were passed, and two samples were lost. Less albumin and less blood were present, and epithelial and blood casts. On April 9th she complained of a good deal of pain over the left eye; the bowels were much distended with gas, and the flatus which passed was extremely offensive. The amount of urine passed was twenty-two and one-half ounces, and three samples were lost; the specific gravity was 1.023, less albumin and less blood were present, and the urine was beginning to look, in color at least, very encouraging. The patient had also been pretty comfortable, and had had a good day, other than the headache she complained of; consequently I arranged to spend the night at home. About ten o'clock that evening she had another very severe convulsion, and this was rapidly followed by four more, before they could be controlled by the chloroform. Much thought and study were given to find out a possible cause for this explosion, and although we thought it a mere coincidence that the convulsion should have occurred after the ingestion of some rice and a little bread and butter, nevertheless we noted the fact and were impressed by the possibility, because the discharges from the bowels were very offensive, and the bowels were quite tympanitic, and the return water after the bowel washes was very foul indeed. The amount of urine passed during the next twenty-four hours, of course, fell, and the dropsy and anasarca again increased, but not much, and only nine and one-fourth ounces of urine were passed and three samples lost. The blood and albumin again increased in amount. We were surprised, however, that the temperature and pulse rate did not show any increase corresponding to that of the first convulsions. The pulse on April 10th, one day after these convulsions, was only 108 to 110, and the temperature 99° to 100° F., and once 98.5°, and the respiration 26 to 34. This strengthened our belief in the possible connection in this case between stomach and bowel fermentation and lessened renal function, and the cause being temporary and quickly removed, the economy suffered but little and for a short time. Bowel antiseptics were administered, and especially the subgallate of bismuth, gr. v. every fourth hour, which corrected the very disagreeable odor, and also indirectly lessened flatus formation. Diuretin was tried but with no effect, and tablets of calomel gr. $\frac{1}{10}$, and sodium bicarbonate gr. i., were given every half-hour for ten doses, with the effect of stimulating the kidneys and acting gently upon the bowels. Three or four times in the earlier part of the sickness these small doses of calomel were given, and always with a good result; but the little one's mouth and gums were swollen and tender, so we had to move cautiously with this agent. Fluids were taken in large amounts, Poland water and Victoria water and broths, making a total of seventy-eight ounces in the twenty-four hours—yet only fourteen ounces of urine were voided. The temperature was only 99° F., yet the pulse was running very high, and oxygen was given; but after a few inhalations the patient refused to take it, so the windows were freely opened and an air bath for one-half hour twice a day was substituted. She, of course, was well covered, and the effect was good. These cold-air baths were continued twice daily for weeks. The heart was showing its great burden, and laboring with a pulse of 152 to 160, and, although regular, was very small and compressible. Citrate of caffeine was injected, gr. ii. every hour for a few doses, then every third; and the brandy, which was a very old and valuable product, was increased to ℥ss. per diem, and diluted with water in agreeable proportions. The restlessness was controlled with the chloral injection, and when the temperature rose above 101° F. the antipyrin was added. The effect of the chloral was always very satisfactory, and proved all through the illness a grand remedy. The caffeine made little impression, so the strychnine gr. $\frac{1}{60}$, and the digitalin gr. $\frac{1}{100}$, were continued as before, and there was added nitroglycerin gr. $\frac{1}{100}$. The urine was carefully watched to see if the blood increased under the nitroglcyerin. It did not, and the pulse got stronger and fuller and fell to 136 to 150, and the temperature remained practically normal. On April 14th the amount of urine passed was eleven and one-fourth ounces and one sample lost; it contained albumin in considerable amount, a few casts with free blood cells attached, urates, blood and epithelial cells.

April 15th and 16th the temperature was elevated to 101.6° F., and it was soon discovered that localized abscesses were developing about the puncture points where the hypodermoclysis was effected. These were opened as indicated, and treated on general surgical principles. The patient was now being nourished by chicken broth, and the whites of five to eight eggs shaken up with water were taken every twenty-four hours, and the peptonized milk ℥iii., and ʒi. of somatose per rectum every fourth hour, and Basham's mixture, two teaspoons, was being taken three times a day.

On April 19th nine ounces of urine were passed and five samples lost. Analysis about as before. From now on the urine increased in amount, and a veritable diuresis existed. She would pass sixty ounces of urine in the twenty-four hours. On the 21st the pulse was 108 to 112, respiration 28, temperature 101.4° F., and forty-four and one-half ounces of urine were passed in twenty-four hours, with a

specific gravity of 1.012; it contained some albumin, but much less than at the previous examinations, urea 0.8 of 1 per cent. to 1.1 per cent., very light in color, but blood-tinged. The patient was now very restless, and had been begging and crying for food for hours. Again a little bread and butter was given her, only three little squares and cut very, very thin, and later a little zwieback. Headache came on in a few hours, and phenacetin was given. The bowels were distended with gas, and a great deal of pain in the belly was complained of, so much so that a rectal tube was inserted into the bowel and the gas let off, and the bowels were again copiously irrigated. Peptonized milk, diluted one to three of water, was again tried by mouth, but in twenty-five minutes this was vomited.

April 21st, in twelve hours eighteen ounces of water were taken, the whites of three eggs, and sixteen ounces of broth. Ferri somatose was substituted for the plain somatose.

April 22d, she continued to take the eggs and nourishment freely, with no headache and no bad symptoms, because no more starchy food had been taken. She passed thirty-two ounces of urine, with a specific gravity of 1.012; four samples were lost. Temperature, 100.6° F.; pulse, 120; respiration, 36–30. The wounds were discharging pus. Bread and butter and rice now being tabooed from the bill of fare, and the little one crying piteously for something to eat, two somatose wafers were given in the day and one at night, and a little zwieback.

April 23d, the report stated that she had had a very restless night, was troubled a great deal with gas and headache, so much so that phenacetin was again given and the rectal tube was introduced. At 2 o'clock A.M. she again had convulsions, and so frequent that five occurred before she could be quieted with the chloroform, and two more some hours afterward when the chloroform narcosis was temporarily suspended. It is to be observed that these convulsions came thirteen days after the last attack, and during the latter five or six days the patient had been doing fairly well. She had passed urine freely. There was some fever, which was no doubt due to the pus developing at the puncture points. A little starchy food was taken, and the headache returned and a diminution in the amount of urea excreted immediately followed, and although the amount of bread and butter and wafers was small, yet they were enough to produce headache and restlessness. Thinking the wafers less dangerous than the bread, they were given in sparing amounts, with a little zwieback, and convulsions followed. The patient was again dry-cupped and poulticed, and the bowels were freely washed out, and the temperature was high, 103.2° to 104° F. She was again put in the cold packs. The pulse was 110 to 136. She passed her urine for the first twenty-four hours involuntarily, and also her fæces.

April 22d, the urine passed for the past twelve hours and only two hours before a convulsion was thirty-two ounces. For the twenty-four hours previous, forty-two ounces; specific gravity, 1.014; trace of albumin; urea, 10 gm. or gr. cl. Indican increased; phosphates and sulphates decreased. Sediment increased—blood, bacteria, an occasional renal cell, some of which are fatty, an occasional granular epithelial and blood cast, a few fibrinous casts (Carpenter). After the convulsion the urine was of about the same character, and contained only 0.4 of 1 per cent. of urea, or about gr. lx. to one quart of water.

Frequent urinary tests were made by Dr. Carpenter for several days, and the urea calculations carefully computed every few hours by myself and assistants, and on May 8th the condition of our little patient was desperate. She was taking water freely and her chicken broth and egg albumen, and the brandy and water, which was now increased to one ounce a day, and the nutrient enemata of ℥ iii. of peptonized milk and ℥ ii. of somatose powder every fourth hour, and retaining them very well. The strychnine and digitalin and chloral had been withdrawn for several days, as there was no necessity for their employment. She was now passing a large amount of urine, pale in color, alkaline in reaction; specific gravity, 1.012; solids normal and only 0.8 of 1 per cent. to 1.1 per cent. of urea. However, in the twenty-four hours the sum total of urea was considerable, as compared with the amount of food taken. Chlorides were slightly decreased, indoxil increased. The sediment was much increased, and consisted principally of earthy and triple phosphates, a little blood, and an occasional hyaline, blood, and epithelial cast—some with red blood cells adherent to them, and an occasional renal cell slightly fatty with a little free fat on casts, a little calcium oxalate, and bacteria (Carpenter).

April 26th, three days after the convulsion, the temperature fell to normal, and the pulse was 66–82 to 90, and she passed two hundred grains of urea, the urea jumping up from ninety grains to two hundred. Nothing but chicken broth and the whites of six eggs and water and the brandy and water were being taken by mouth, and the nutrient enemata, showing conclusively that the kidneys could and would do their work if not interfered with in their function by some paralyzing or inhibiting poison. Urea calculations were now made every second hour night and day, or as often as urine was voided, and always after any additional amount of nourishment had been taken, and if a corresponding increase of urea resulted after the increased amount of food, then the food was continued or withheld for a few hours.

April 27th, P., 80 to 68; T., 98.4° to 99.6°. April 29th, P., 66 to 72; T., 98° to 98.4°. April 30th, P., 66 to 74; T., 98° to 99°. May 3d, P., 66 to 74; T., 98° to 99°. May 5th, P., 56 to 68 to 74; T., 98° to 99°. May 11th, P., 66 to 86; T., 98° to 99°. May 16th, P., 72 to 84; T., 98.6° to 99°. May 18th, P., 78 to 114; T., 98.6° to 99°. May 20th, P., 84 to 100; T., 98.4° to 99°. May 23d, P., 94 to 110; T., 98.4°.

The pulse, as you see, was abnormally slow for weeks, and I am now of the opinion that some toxin or urea derivative was retained in the system which inhibited the heart's action. We know that certain urea products make coma; others, restlessness and convulsions; and why may there not be others which depress the heart's action? There can be no other explanation for such a slow heart in a child dying from starvation. When the kidneys began to throw off a large amount of urea under the more generous diet, we see the heart went up to 94 to 110, where it remained for many weeks. The pulse now runs from 88 to 96. The patient was on the brink of dissolution, and a more wasted and emaciated body I had never seen, with a pulse of 60 to 68, and a temperature of 98°. For some days past the question of again trying milk by mouth was seriously discussed, and every one of us being satisfied that death was inevitable if more food was not given the child, the milk two or three times diluted with water, ice-cold, was again tried. The stomach and bowels had been rested for many days, and the kidneys had no doubt in a measure rehabilitated themselves, because the milk diluted with twice the amount of water was retained and enjoyed. It was cautiously increased, and on the 15th she took sixteen ounces of broth and forty-eight ounces of milk in twenty-four hours, besides the nutrient enemata. She took care of everything, and the amount of urea excreted made a jump, and before long she was passing over five hundred grains in twenty-four hours. The nutrient enemata were now stopped, because the amount of food was every day increased.

It was being digested and taken care of, because the urea calculations showed a proper equivalent, and the child rapidly grew in strength, flesh, and spirits. She was always hungry and took her food with avidity, and always begged for more, and on May 25th she passed 2,070 c.c. of urine, or four pints, and 41.4 gm. of urea (621 grains). Total solids, 101 gm. (for an adult 70 gm. is a good amount). Color, pale, alkaline; specific gravity, 1.021; slight trace of albumin; indoxil normal; chlorides normal (relatively); alkaline phosphates decreased; sulphates normal; sediment much increased in amount, principally triple phosphates, bacteria, few red blood cells, renal cells, and leucocytes. The food on this day was prodigious, and consisted of bread and butter, six soft-boiled eggs, forty-eight ounces of milk, twelve ounces of broth, two chops, and eight ounces of junket. She soon gained strength, sat up, and went downstairs for her first dinner on June 10, 1900. The improvement continued, and the chemistry of the urine was every day more encouraging, and in July she weighed seventy-six pounds, ten pounds more than ever before in her life, and to-day is a strong, handsome, well girl.

It is interesting to note how in a few days the amount of urine passed increased from twelve and sixteen ounces to sixty unces and over per diem; in fact, a veritable flushing existed. She passed on May 10th, 67¾ oz. urine, 207 gr. urea; May 15th, 91½ oz. urine, 350 gr. urea; May 19th, 80 oz. urine, 461 gr. urea; and there was taken milk 54 oz., broth 30 oz., somatose 2½ drachms; in the broth, whites of six eggs, 12 oz. water—in all, 96 oz. fluid. May 25th, 69 oz. urine, 630 gr. urea; May 26th, 66½ oz. urine, 581 gr. urea; June 10th, 51 oz. urine, 526 gr. urea, specific gravity, 1.018; June 14th, 43 oz. urine, 451 gr. urea, specific gravity 1.019; with only the slightest trace of albumin and seen only by the most careful inspection, an occasional renal cell and blood cell, and no casts. June 23d, 46 oz. of urine.

And now let me summarize and apply my deductions from this interesting and remarkable experience, and thus place the matter in a succinct manner before you for discussion.

1st. Every case of scarlet fever is a law unto itself.

2d. Convulsions may occur and do occur when least expected and every case of scarlet fever should be closely watched for many weeks.

3d. The urine should be frequently examined, not only its specific gravity taken and albumin tested for, but urea calculation should be often made.

4th. Mere specific gravity is not a sufficient indication as to the amount of urea eliminated, because the specific gravity may be fairly high, and yet urea can be retained in poisonous quantities; moreover, a large quantity of water can be voided and with a fair specific gravity, and yet convulsions may occur.

5th. Albumin need not be present, or only a trace may be found in the urine, yet convulsions may occur, but the albumin will be found perhaps in great amounts after the convulsions have occurred.

6th. Only the most digestible food and nourishment should be given, and if possible such foods as produce little gastric and intestinal putrefaction; the food par excellence being milk, because the amount of toxalbumins and putrefactive residue is reduced to a minimum.

7th. If milk cannot be digested or will not be taken, no food should be administered for days by the stomach, simply an abundance of water and the patient nourished by nutrient enemata. If broths are borne, chicken broth, made after the directions of Dr. Pryor of New York, as found in his book, is a pleasant and, I am satisfied, nutritious food.

8th. In any severe case of convulsions, only small amounts of nourishment, if given by the stomach, should be attempted at any one time, and frequent urea calculations should be made to see that the proper quota or equivalent of urea is eliminated, and if the urea is not increased after the ingestion of the food, then the food must be withheld or such food be substituted as will not interfere with the proper excretion of urea.

9th. If gastric irritability exist, give the stomach and bowels rest, because by giving them rest, a period of quiet also results for the kidneys, and that interval of time may be sufficient to permit the kidneys to rehabilitate themselves, either in function or to develop new renal secreting cells, as scarlatinal nephritis is a desquamative process, and new epithelial cells are no doubt often quickly formed.

10th. The amount of urea passed in twenty-four hours differs in different individuals, and it may roughly be stated that an excretion of 10 gm. or gr. 150 of urea for a child ten years old, weighing sixty pounds, will protect her from convulsions. My patient is to-day passing over five hundred grains of urea every twenty-four hours.

11th. Hypodermoclysis is a very valuable and safe method to introduce water into the system, and as much as two or three pints can be used, and with proper precautions no danger will result or severe abscess formation follow. The decinormal salt solution should be used, and should be first boiled, and the skin is to be thoroughly disinfected by washing it freely with soap and brush, and then washing again with bichloride solution 1:2,000, and subsequently with alcohol. The needle and fountain syringe with tube should be placed in boiling water and boiled for a few minutes to insure their perfect cleanliness.

12th. Enteroclysis, or the introduction into the bowels of a number of quarts or even gallons of water, of a temperature ranging from tepid water to water of a temperature of 80°, if much fever be present should be employed once or twice during the twenty-four hours.

13th. Strychnine, and digitalin are our most valuable heart stimulants, and brandy is our best food and diffusible stimulant.

A Case of Latent Puerperal Convulsions, Occurring Three Weeks after Delivery, and Presenting no Premonitory Symptoms of Uræmic Poisoning.—The patient of T. A. Martin was a woman of twenty-seven who passed through her seventh confinement without incident and was up and about on the twelfth day. Ten days later she suffered from severe infra-orbital neuralgia, which was cured in about a week. One week after that she was taken with clonic spasms suggestive of uræmia. The urine was found loaded with albumin. Pilocarpine, morphine, bleeding, etc., were all tried, but without definite relief. Examination of the blood showed plasmodia malariæ, and the patient was put on quinine. Under this she slowly improved, but later there was an inflammation of the veins of the leg which retarded recovery. She was finally discharged, cured, about three months after her confinement. The author calls attention to the late appearance of the convulsions after labor; to the absolute want of any premonitory or uræmic symptoms occurring before the convulsive seizure; the recurrent convulsive seizures; the obstinacy of the trifacial neuralgia; the presence of the malaria parasite in the blood after each convulsion; the occurrence of double phlegmasia alba dolens; hemiplegia lasting four days; and the ultimate complete recovery of the patient from all these unusual complications.—*St. Louis Courier of Medicine*, December, 1900.

Spontaneous Dislocation of the Hip Occurring during Typhoid Fever.—L. A. Weigel reports the

case of a girl of eight who in the sixth week of her fever complained of severe pain in both hips, but more marked in the right one. The pain gradually ceased in the left hip; the acute symptoms in the right one, however, continued. The joint became markedly swollen and tender. The acute joint symptoms, together with the position of the leg in flexion and adduction, rendered a diagnosis of coxitis justifiable. On account of the marked asthenic condition of the child at this time, however, a satisfactory examination to determine the exact nature of the trouble could not be made. The more acute joint symptoms gradually subsided and after the child had been ill for eleven or twelve weeks she recovered from the fever and subsequently was able to get about on crutches. When seen four months later the contour of the hip and posture of the leg closely simulated the appearance of a case of hip disease in the third stage. The leg was flexed, adducted, and rotated inward, and three and one-half inches shorter than its fellow. The usual limitation of joint motion and other typical symptoms of coxitis, however, were absent, and as the trochanter was well above Nélaton's line, it was evident that the femur had become dislocated upward on the dorsum of the ilium. The existence of the suspected lesion was confirmed by radiograph.—*St. Louis Courier of Medicine*, December, 1900.

Prophylactic and Curative Treatment of the Bubonic Plague in India.—A. Lustig and G. Galeotti describe the preparation and composition of the serum which they use. Their experience during the past four years has proved that it is the only serum which gives perfectly satisfactory results. It has been recommended for use by the sanitary authorities in Bombay, and is the only serum produced in a special laboratory there, being widely used in hospital and private practice, whereas other serums have been discarded.—*Lo Sperimentale*, vol. 54, No. 8.

Some Remarks on the Pathology of Gastric Ulcer.—Charles J. Nepean Longridge says that experimental evidence confirms the view that ulceration of the stomach may depend on toxic causes, for Enriquez and Hallion, by injecting diphtheritic toxin under the skin of guinea-pigs, produced undoubted gastric ulcers. Moreover, Flexner, in his researches upon toxalbumic intoxication, found small ulcers in the stomach on several occasions among other structural changes. The occurrence of such ulcers depends upon the fact that the stomach, among its other functions, includes that of an excretory organ. Exactly how the poison, in the course of its excretion by the gastric mucosa, causes death of the cells with which it comes in contact is a wide matter for discussion. Such a condition, however, exists, although it is more of pathological interest than of clinical importance.—*Treatment*, December, 1900.

A Case of Carcinoma of the Pharynx with Marked Involvement of the Cervical Glands in a Boy Fourteen Years of Age.—J. M. Elder reports a case in which the prognosis is hopeless. As regards the etiology he says that he cannot do much more than put down the questions that have occurred to him. How much has heredity to do with it? The mother showed symptoms of cancer when the child was four years old, and died from it two years later. How long has the cancer existed unnoticed in the pharynx? Was it the cause of, or was it possibly aggravated by "catarrh" noticed by his friends? And, finally, in what tissue did it begin? Cancer of the faucial tonsils is well recognized. Did this possibly begin in the pharyngeal tonsils while they were undergoing atrophic changes? One would expect to find in this region a sarcoma or an epithelioma, but carcinoma is rare, especially when the age of the patient is taken into account.—*The Montreal Medical Journal*, December, 1900.

A Rare Disease Characterized by Subcutaneous Phosphatic Concretions.—M. Jeanne describes the case of a young shepherd of twenty-five years, suffering from cutaneous and subcutaneous generalized lesions, formed of concretions, ulcerations and fistulæ, and cicatrices. The concretions would first appear as hard, painless tumors beneath the skin, irregular in shape and size, free from the epidermis and the derma. Later they invaded the skin and finally caused ulceration. Small particles of sand or stones the size of peas came out of the ulcers. There were muscular atrophy, diminished mobility of the larger joints, and certain trophic disorders. The patient died under chloroform, given for the purpose of cleansing and draining the extensive suppurations of the left thigh. At the autopsy, the only abnormalities found were intestinal ulceration and the concretions described. They were found to consist of carbonate of lime 6.8 parts, phosphate of lime 67.7, organic matter 23.4, phosphate of magnesia 2.1. The author inclines to the opinion that the trouble is of parasitic origin.—*Bulletins et Mémoires de la Société Anatomique de Paris*, November, 1900.

Concerning the Etiology of Asthma.—John Dunn believes that asthma is not a reflex of the swollen turbinates or of the ethmoiditis with its polypi, but of the intense irritation caused by the action on the mucous membrane of the metabolic products. This irritation may cause reflex asthma in a person whose nasal mucous membranes are, between the asthmatic attacks, perfectly healthy so far as can be judged by the naked eye. It may be so intense as to cause ethmoiditis and thus beget nasal polypi. Hay fever is a direct expression of this irritation. The two diseases are thus closely connected and not infrequently coexist in the same individual. The writer does not use the term uricacidæmia as a descriptive term, because he does not believe that uric acid is the only product of tissue metabolism which when retained in the tissues is capable of producing irritating effects. He believes, however, that it is the chief product in bringing about asthmatic disturbances.—*Charlotte Medical Journal*, January, 1901.

The Possibility of Cure in Progressive Paralysis.—Raffaele Pisani reports a case in which apparent recovery occurred. He says that of course it might be considered an unusually prolonged remission of symptoms, having lasted seven years with *restitutio ad integrum*. It is not usual in progressive paralysis to see certain symptoms disappear, as for instance pupillary disorders, tremor, motor disorders of speech, or even graver psychical disturbances. This fact has not unnaturally led to the conclusion that progressive paralysis is a disease of toxic origin, in which there is a possibility that the toxin might be eliminated from the nerve tissue and that anatomical lesions, if not too far advanced, might be cured.—*Giornale Internazionale delle Scienze Mediche*, December 31, 1900.

Subcutaneous Auto-Grafting of Ovaries following Salpingo-Oöphorectomy.—P. Mauclaire says that in many cases it is desirable to preserve the whole or part of an ovary, with a view to the avoidance of the local and systemic disturbances which frequently follow their removal. He has, therefore, in several cases engrafted the ovary into the abdominal wound or under the skin with fair results. Sometimes the ovary is infected, in which case it will have to be removed. This process of grafting can be done to advantage even after the menopause.—*La Gynécologie*, December 15, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, February 23, 1901.

PULMONARY TUBERCULOSIS AS A CAUSE OF DEATH.

TUBERCULOSIS, especially involving the lungs, is so widespread a disease and so large a factor in the death list that any knowledge concerning its activity cannot be considered unimportant. Material reductions have been brought about in its prevalence and its fatality; and with a better and fuller comprehension of its causes, and consequently of its preventability as well as cure, the ravages of the disease should be still further restricted. Some interesting statistics bearing upon this question are analyzed by Thomas Oliver (*Lancet*, November 10, 1900, p. 1335) in a lecture on the physiology and pathology of inheritance, delivered at the opening of the course of clinical medicine at Newcastle-upon-Tyne Royal Infirmary. The fact was pointed out that between 1858 and 1860 the average number of deaths annually from pulmonary tuberculosis in England and Wales was 2,565 per million, while between 1871 and 1875 it was 2,218; between 1886 and 1890, 1,635; in 1891, 1,599, and in 1892, 1,468. This reduction in mortality from a single cause cannot but be a source of great gratification to all interested in the welfare of the race, in the prevention of disease, and in the preservation and prolongation of life. The hope seems not unjustified that a more widespread diffusion of knowledge concerning the mode of dissemination of tuberculosis, and therefrom a more intelligent appreciation of methods of prevention, must continue to result in further reduction in both the incidence and the fatality of the disease.

According to the mortality records of the Mutual Life Insurance Company of New York, dealing with 46,525 deaths between 1843 and 1898, it appears that the rate of mortality from all causes rises with advancing age, and the same diseases that affect youth carry off persons in old age. Of the whole number of deaths, tuberculosis caused 5,585, all but 133 of which were due to disease of the respiratory organs. The mortality rate from tuberculosis was high at early ages, diminishing with advancing years, although still observed in extreme old age. Of each 100 deaths from tuberculosis, 59.2 per cent. occurred before the age of forty-five; 28.94 per cent. between forty-five and sixty, and 11.85 per cent. after sixty; while tuberculosis caused 24.27 per cent., 10.88 per cent., and 4.03 per cent., respectively, of the total number of deaths during the periods named.

Further analysis shows that the greatest number of deaths from pulmonary tuberculosis occurred before the age of thirty, as well in families with as in those without a history of that disease, though larger in the former for every decennial period of life to extreme old age. On the other hand, the ratio of mortality among the total causes of death diminishes with advancing years, owing to the fact that other diseases make their influence felt. Pulmonary tuberculosis claims its victims in largest number in the early years of manhood, for after middle age degenerative diseases of the circulatory organs and the nervous system make their appearance and relegate tuberculosis to a less conspicuous position. According to the experience of the Scottish Widows Fund, the age of thirty-five years is that at which the largest number of deaths from pulmonary tuberculosis occur.

THE TREATMENT OF INSOMNIA.

IT need scarcely be said that loss of sleep is merely a symptom, arising from a multiplicity of causes, singly or in varying combination, and that the best treatment will be that which is directed to a removable cause. The symptom may at times, however, be the most conspicuous clinical manifestation, and its cause may elude the most rigorous scrutiny, while its persistence may make it a serious complication from which relief must be secured by means directed specifically to that end. In a clinical lecture on the causes and cure of insomnia, Sir James Sawyer (*British Medical Journal*, December 1 and 8, 1900) describes sleep as an appetite—that is, a craving produced by the recurring wants and necessities of bodily or organic life. Its two striking characteristics are its periodic recurrence and its organic necessity. If resisted, uneasiness, discomfort, and pain result.

It is probable that sleep is due in part to intrinsic changes in the ultimate tissue elements of the brain that are concerned in consciousness—perhaps induced by the products of tissue waste—and in part to diminished supply of blood to the brain. It is to be borne in mind, however, that not only the brain but the entire body is at rest during sleep.

Among the conditions to which derangements of sleep may be due are pain, elevation of temperature, cough, and dyspnœa, singly or in varying combination; and the treatment will have to be directed to the underlying cause, in addition to the administration of hypnotics under appropriate conditions. At other times no obvious cause for the disturbance of sleep can be discovered, but this may be inferentially sought in psychic, toxic, or senile processes. Thus, sleep will be prevented if the brain-cells, instead of entering upon a natural period of repose, continue in their usual or unusual activity. This will necessarily be associated with relative cerebral hyperæmia, and this in turn will act as an accessory cause of the inability to sleep. On the other hand, the disturbances in cerebral circulation—from whatever cause—may be

the principal factor, and these may excite increased cerebral activity, the combined influences operating to prevent sleep.

Insomnia of psychic origin occurs most commonly in individuals of a nervous temperament—namely, those with great sensitiveness and activity on the part of the nervous system—and especially in men. It may result from emotional disturbances, such as grief, or from mental strain, acute and overwhelming or moderate and prolonged. The symptom may then be attributable in large part to vasomotor paresis of the intracranial blood-vessels as a result of exhaustion, probably induced by unnatural excitation of the cerebral cells. Insomnia of toxic origin is due to the action of some noxious agent that produces cerebral hyperæmia. The most important of the poisonous substances acting in this way are alcohol, tobacco, tea, and coffee, together with the waste products of imperfect metabolism, as witnessed in the presence of gout and disease of the kidneys, and possibly also in auto-intoxication from the gastro-intestinal tract.

Insomnia of senile origin is essentially due to cardio-vascular influences, as for instance, degeneration of the small cerebral vessels. This condition results in permanent dilatation of the vessels, although the latter may be largely counteracted by the cardiac enfeeblement often also present.

In the treatment of insomnia the most important indication is to ascertain the underlying cause, and, so far as possible, to secure its relief. Hypnotics should be resorted to only as they become absolutely necessary. Of these, opium and its derivatives and chloral can be depended upon, and the use for a short time of one or another of these may quickly cure acute insomnia due to sudden mental shock or strain. Among other hypnotics are sulfonal, trional, paraldehyde, amylene hydrate, and the bromides; alcohol and cold affusions to the head may exert a similar effect. Sometimes a combination of two or more hypnotics is more efficient than any single one. It seems scarcely necessary to issue an injunction for the exercise of great care in the employment of hypnotics in order to avoid habituation and other undesirable effects; and particularly should the indiscriminate or capricious use of such drugs by patients be guarded against.

Not less in the prevention than in the relief of sleeplessness should overwork or working under improper conditions be avoided. It is, however, to be borne in mind that more often worry, rather than work, is the real cause of the inability to sleep. A suspension of work, with change of scene and activity, will, in any event, contribute to a successful result.

Potassium bromide is considered by Sawyer by far the best hypnotic for well-nourished patients and the slighter cases generally, being a direct and safe brain sedative and producing nervous calm. From gr. xxx. to gr. lx. dissolved in water should be given after the patient has gone to bed. It may advantageously be combined with tincture of ergot or tincture of digitalis, or both. In the presence of anæmia, iron or arsenic or both will be required, together with a generous diet, including fish, meat, and eggs. Under such circumstances alcohol often acts well as an hypnotic. Here also caution should be observed, to avoid habituation.

To secure good results both in health and in disease it is important for the individual to retire and to rise at a fixed and regular time. A nap of half an hour or so in the afternoon after a meal is helpful and favors rather than hinders good sleep at night. Bodily exercise in the open air daily—but always short of fatigue—is to be commended. This may take the form of driving, walking, cycling, or riding, or outdoor gardening. For those who live in cities various physical exercises and drills, fencing with foils, and the like, may be advised. Free and long daily exposure to the sun is a valuable adjuvant.

If the inability to sleep is due to the habit of thinking on getting into bed, some monotonous exercise may be practised, such as counting consecutively up to a high figure; picturing a familiar scene, and keeping the mind fixed upon it; constantly repeating the letters of the alphabet; or taking deep inspirations. The bed-clothing should be sufficient, but not excessive. The bedroom window should be open throughout the night, but draught is to be avoided. The head of the bed should be away from the wall. The best bed consists of a hair mattress covered with a sheet and blanket and supported on springs. In some cases a little food taken on retirement acts as an efficient hypnotic. Sleep may often be induced by the temporary application of cold to the head or to the general surface of the body.

THE GERMAN ARMY MEDICAL SERVICE.

THE Germans have gained a world-wide reputation—which, indeed, has been fairly earned—of being thorough and painstaking in their methods of organization in business, in education, and in most other pursuits of life. Considered from this point of view, the management of their army to its minutest details stands out even in that land of system high above all other organizations, and is an object lesson to every nation. The German military scheme of arrangement is admitted on all hands to be the most perfect of modern times, and the condition of the army medical service is in keeping with this generally high state of efficiency. Much time, intelligence, and money have been expended in evolving the magnificent machine known as the German army, of which assuredly its not least important wheel is the medical corps. At a period when the need for the medical service of armies to be placed on a thoroughly stable and serviceable basis has received such ample demonstration in this and in other lands, and when the decision has been come to, to reform and enlarge the army of the United States, it is fitting that the medical journals should take up and advocate the cause of the army surgeons. Convincing proof was afforded in our Spanish war that, however willing and able the surgeons, both military and civil, serving with the colors might be, they were unable to cope successfully with the difficulties which confronted them. Presumably this state of affairs was to a large extent due to lack of proper system. In the

Albany Medical Annals of January, 1901, Dr. Andrew MacFarlane reviews the existing status of the Germany medical army corps, and draws contrasts between that body and those of other nations, by no means flattering to the latter. While we may not agree, perhaps, with all that Dr. MacFarlane advances, and consider that his eulogy of the conduct of German medical military affairs is somewhat too roseate, at the same time it cannot be denied there is a solid substratum of truth in all his remarks and criticisms; and it will be freely granted by probably the majority of American physicians that all countries could with advantage learn a useful lesson from the practical Teuton with regard to these matters. There is little or no difference in the training of the military and civil surgeons in Germany. The Kaiser Wilhelm Academie, established in Berlin and well endowed by the then emperor of that name, is the school at which the embryo army surgeons receive a part of their instruction. This academy, according to Dr. MacFarlane, at present has two hundred and seven students chosen after competitive examination, modified to some extent by family influence, from all parts of Germany except Bavaria and Saxony, which still retain the control of the organization of their armies. They receive from the State free lodging and tuition and 30 marks monthly. For medical books, preparations, and instruments the student pays one-third and the State two-thirds. After the regular medical course, which is amplified by special instruction, and quizzes by army surgeons, they have one year's service in the Charité, rotating in the different services. They are then assigned to duty as assistant surgeons. After some years' practical service in army hospitals, attached to regiments or in the colonies, they are ordered back to Berlin for post-graduate study. If they show an especial aptitude for scientific research they may be appointed assistants to the different professors. They can then resign from the army and devote themselves exclusively to medical science. The result of this training is at once seen in the professional standing of the men who have been thus developed. The roster of graduates shows the names of v. Helmholtz, Virchow, v. Winckel, v. Leyden, Nothnagel, Gaffky, Loeffler, Hueppe, Renvers, Behring, Goldscheider, Widenmann, whose reputations are international, and of a host of others who are physicians of acknowledged high repute. Every word of the foregoing statement is true, and, as remarked before, many of the German methods of military medical organization might be adopted in this country with corresponding benefits to all concerned. Nevertheless, the fact should not be lost sight of that the positions of the United States and Germany are very different. The last-mentioned country is compelled by her geographical situation to support an immense army; therefore, she is quite right to insist that so important a factor in war as her army medical corps should be kept at the highest possible state of efficiency. Here an army by comparison extremely moderate in size will suffice, as it is improbable that any land war of any considerable magnitude will be undertaken or forced upon the United States. Notwithstanding these facts, it would be an act of wisdom on the part of the government to order that the army should be complete in every detail; and that in particular so vital a part as the army medical corps should be in no respect neglected. Especially might those who have the guidance of the affairs of our nation take the German army medical system as a model regarding matters hygienic. This is a point which really directly concerns us at the present time. In the German military expedition to China the medical care of the troops will be looked after in the most sedulous manner. Officers have been ordered to instruct their men with regard to sanitary matters. Sterilizing apparatus of the most approved type have been supplied, and army medical officers well versed in bacteriology will accompany the troops for the purpose of examining food and water and of investigating any suspicious causes of disease. The medical corps, too, will not be hampered for lack of members, there being one medical officer for each one hundred and twenty-nine men. No expeditionary force has ever been sent out better equipped from a medical standpoint, and much should be learned by Americans and others from the study of mortality from disease in the armies of various nationalities now operating in China.

FRACTURES OF THE SPINE.

In the medical and surgical reports, Boston City Hospital, series xi., 1900, there is a descriptive report of five cases of fracture of the vertebræ, in two of which an operation was done. Very careful gross and microscopical examinations were made, and the cases are of great interest on that account, though they are not encouraging from the therapeutical point of view. All were fatal, and operation did not seem to have any particular effect upon the time or manner of the issue. Four of the cases showed fractures and displacements of one or more of the lower cervical vertebræ, and one the same sort of injury in the upper dorsal region. The autopsies showed that in cases of this kind, as all observers have noted, there is always considerable displacement of fragments which is the determining factor in the amount of crushing sustained by the cord. In these cases the two operations were accomplished without great technical difficulty or danger, and the pressure was removed, but both patients died, one twenty and the other twenty-five hours after operation. Both had fractures in the cervical region. In the case of the three other patients no operation was deemed advisable, on account of bad general condition in two instances, and the fact that in the third the patient was actually moribund when admitted to the hospital. These cases are interesting to both the neurologist and the surgeon. From the point of view of the neurologist, the questions of diagnosis and prognosis are those that require decision, while surgically speaking the value is in showing that, in the presence of certain evidences of injury to the cord, there is practically nothing to be gained by operating, though the operation itself is perfectly feasible. It seems to be a fact that the spinal cord is even more sensitive to a bruising force than was supposed to

be the case when the matter was first extensively studied a few years ago; and also that when the substance of the cord is actually contused and infiltrated with minute extravasations of blood over one or more complete segments, there is no hope of a real restoration of function. In this report, attention is called to the fact that abolition of the patellar reflex indicates an extreme degree of injury to the cord. This is undoubtedly the case, but many patients in whom this reflex has persisted after injury have been operated upon, and a hopeless degree of crushing has been found, so that in this fact there is no important favorable element of prognosis, but only an indication that the crushing of the cord is not absolutely complete. It seems that the structure of the spinal cord is so delicate that even a temporary serious interference with its internal circulation, not to mention actual laceration of tissue, involves the practical certainty of irreparable damage, to the nerve cells especially, from which in a few of the more favorable instances a partial recovery may take place. The least unfavorable condition which we may expect after an injury with paraplegia is hemorrhage outside the cord, either in the pia mater or between the dura and the bone, without any injury to the cord except that caused by pressure. This comparatively unusual condition is not likely to occur if there is fracture, and without fracture operative treatment would be recommended with considerable hesitation. We can, however, say with certainty that if a patient shows complete paralysis and loss of sensation in all its forms in the region innervated from the cord below the injury, and if there are no variations in the symptoms, then the cord is hopelessly injured and an operation will do no good. Cases of this kind do badly from the first, and a fatal outcome is not usually postponed many days, especially when the injury is in the upper dorsal or lower cervical region. The diagnosis in this sort of case is not difficult, and we are compelled, when confronted with such symptoms, to give an immediate but reluctant unfavorable prognosis. It is furthermore unfortunately true that in most cases of serious injury of the spine the symptoms are of this unfavorable kind, and it is only in a few rather uncommon instances that we can operate with any hope of considerable and permanent good. When there are signs that the cord has not been absolutely severed, when the patellar reflex remains, and when there are variations in the symptoms, especially sensory, and if the osseous signs of fracture or dislocation are present, we may operate with a prospect of success which is, however, only fair. Even if we are able by operation to prevent any extension of the injury, the chances are that there will be no important improvement in the general condition, though from the patient's point of view the least improvement means much. It must be remembered that some patients with spinal injuries involving paralysis improve to a certain extent without operation, and we should not be too ready to claim a great deal for our treatment when improvement after operation is only slight. The present status of these cases of spinal injury seems to be expressed by saying that nothing can be done for those patients who have the symptoms of crush of the cord at any level, while in other patients the advisability of operating must depend on the apparent requirements of the individual case, with the chances of doing much good at best but dubious. With our present instruments and technique the actual performance of the operation presents no particular difficulties. Much can be done for a patient who shows any inclination toward improvement after laminectomy, by nursing, massage, and some form of electro-therapeusis.

News of the Week.

Harlem Hospital, New York.—Dr. John J. McGrath has been appointed attending surgeon to the Harlem Hospital.

Medical Society of the Missouri Valley.—The semi-annual meeting of this society will be held in the City of Omaha, on Thursday, March 21st. A number of excellent papers have already been promised, and indications point to an interesting meeting.

Prize Essay on the Dangers from Quackery.—The Colorado State Medical Society offers a prize of twenty-five dollars for the best essay, if deemed worthy of the prize, pointing out the dangers to public health and morals, especially to young persons, from quackery as promulgated by public advertisements. The competition is open to all. Essays must be typewritten in the English language, and submitted before May 15, 1901. Each essay must be designated by a motto and sent to the Literature Committee, Room 315, McPhee Building, Denver, Col.

Prospect of a State Board of Health in Texas.—The *Galveston News*, December 23d, reports the adoption of a resolution by the Democratic Convention at Waco, on December 22d, as follows: "Resolved, That we favor the creation of a State board of health with the provision for the collection of vital statistics of the State as provided for by the constitution, article 16, section 32, and the enactment of laws to distribute the expenses of improvement of quarantine equitably between the State, counties, and municipalities." The Texas State Medical Association has appointed a committee to draft a bill creating and defining the powers of a State board of health as contemplated by the resolution. Its scope is expected to enlarge and make more efficient the State Health Department than it has ever been heretofore.—*Sanitarian.*

Smallpox in Glasgow.—The extension of the smallpox epidemic, says *The Lancet's* Scotch correspondent, writing on January 29th, is assuming serious proportions. On January 27th eleven new cases were admitted to hospital, making a total of three hundred and seventy-eight under treatment. The disease for the most part is not of a severe type, but there have been over a dozen deaths. An anxious feature of the epidemic is its widespread character. Cases have been detected in nearly every quarter of the city, and the neighboring boroughs and townships are also beginning to suffer. It is feared that the disease will spread more widely.

Increase in Vienna's Population.—The official census of Vienna shows that the city numbers 1,635,647 inhabitants, an increase of 300,000 in ten years.

Grippe in North Carolina.—The damp, murky weather in North Carolina is reported to be breeding grippe rapidly, and in many cases it is followed by pneumonia.

Famine Feared in Russia.—The Ministry of the Interior announces the complete failure of crops in all parts of Russia. Relief has been organized, but private charity is needed.

Free Baths in Public Schools.—Public School No. 2, at the corner of Oliver and Henry Streets, has introduced free baths for any of its scholars who wish for or need ablutions. This innovation is worth a trial, and if successful in School No. 2 will doubtless be adopted in other schools.

Professor Pickering Honored.—The gold medal which is given annually by the Royal Astronomical Society has been awarded for the year 1900 to Prof. Edward Charles Pickering, professor of astronomy and director of Harvard College observatory since 1877, for stellar photography.

To Stop Christian Science Practice in Alabama.—The State legislature on February 8th enacted a law prohibiting Christian Scientists and faith-cure doctors from doing business in Alabama, and imposing a heavy penalty for violation of the law.

Philadelphia Pediatric Society.—At a stated meeting held February 12th, Dr. J. D. Target reported "Two Cases of Jacksonian Epilepsy." Dr. J. P. Crozer Griffith exhibited (1) "A Case of Splenomegaly with Enlarged Liver;" (2) "A Case of Probable Tuberculous Peritonitis;" (3) "A Case of Congenital Cyanosis." Dr. J. H. Jopson exhibited "A Case of Nodding Spasm with Wry-neck in a Rachitic Child." Dr. D. L. Edsall read a paper entitled "Gumma of the Liver in a Child of Fourteen Years." Dr. J. P. Crozer Griffith described "A Convenient Plan for Bedside Case-History Taking in Private Practice." Dr. Emory Marvel read a paper on "Suppurating Mastitis in the New-Born." Dr. T. S. Westcott presented "A Note on the Differential Modification of the Proteids of Milk." Dr. J. A. Scott made "Some Remarks on Intestinal Sand."

The Prevention of Tuberculosis in Germany.—United States Consul Monaghan, at Chemnitz, reports to the Department of State that the German Department of the Interior has issued a set of instructions conveying compulsory precautions to be taken against the spread of tuberculosis in the empire. The instructions consist of articles providing that doctors under all circumstances when their patients have lung or larynx tuberculosis must give written notice to the police as soon as the case in question has been diagnosed; that immediately after the death of a person from this form of disease, the room and effects of the deceased must be thoroughly disinfected; that professional women who lay out the dead must report at once in writing to the police authorities whether the disease was of the lungs or larynx; and that keepers of hotels, lodging-houses, asylums, or other public institutions shall report immediately the appearance of the disease in the establishment under their control. Non-compliance with these regulations is subject to a fine of $35.70 or six weeks' imprisonment.

Work at the German Hospital.—The thirty-first annual report of the board of trustees of the German Hospital and Dispensary was made public recently. The hospital was taxed to its utmost last year, and the frequent turning away of patients made it necessary to consider the enlargement of the hospital buildings. Work on an annex was begun in April, and the addition is now so well advanced toward completion that it is expected it will be finished in June. Last year 3,852 patients were treated in the hospital. Of these, 2,447 were free patients. In the dispensary 22,595 patients received treatment free of charge. Legacies received aggregated $10,047.50, and donations amounting to $4,963.80 came in. Among the receipts were $3,630, the proceeds of the concert given by the Arion and Liederkranz societies; $1,300, which came from the German Charity ball, and $3,461, which was sent by the Hospital Saturday and Sunday Association.

College of Physicians of Philadelphia, Section on General Medicine.—At a stated meeting held February 11th, Dr. J. Allison Scott presented a man thirty-three years old with a history of syphilis and exhibiting physical signs of aortic obstruction and regurgitation, and a pulsatile swelling in the back between the left scapula and the vertebral column, at the level of the spine of the scapula. Dr. William G. Spiller presented "A Case of Amyotrophic Lateral Sclerosis of the Scapulo-Humeral Type." He presented also a photograph of "A Case of Facial Palsy," probably of central origin, with irritative phenomena in the form of spasm in the distribution of the superior branch of the nerve; and further, the photograph of "A Case of Extensive Peripheral Neuritis," probably due to the combined effects of alcohol and lead. Dr. Spiller exhibited also a case of almost isolated "Palsy of the Anterior Tibial Muscle," probably due to pressure. Dr. D. L. Edsall read a paper entitled "Methods of Examining the Gastric Contents." Dr. D. J. McCarthy read a paper entitled "Vascular Degeneration as a Family Disease, and its Relation to Migraine." He reported a family in which the mother presented at first symptoms of migraine, to which subsequently became added manifestations of an epileptiform character on the opposite side. Several of the woman's children presented evidences of a hemorrhagic tendency.

Army Medical Examinations.—As a result of the reorganization of the army by act of congress approved February 2, 1901, there are one hundred and twenty-nine original vacancies as assistant surgeon to be filled. The prescribed age limit of candidates will be rigidly adhered to, and it will be useless for those who are more than twenty-nine years of age to apply, unless they have had previous service as mentioned in

the army circular. The requirement of hospital experience or its equivalent in private practice will also be insisted upon. Hospital work as a student will not be regarded as fulfilling this requirement; experience as a physician after graduation is what is meant. Two years of private practice will be considered an equivalent of one year's hospital experience. Army medical boards will be convened at an early day in Washington and in San Francisco, and examinations will be begun as soon as possible. Copies of the official circular may be obtained upon application to the office of the surgeon-general of the army, Washington, D. C.

Hospital for Red Cross.—A hospital and training-school will be erected in Central Park West by the New York Red Cross Society, which has already bought the ground for $100,000. The building is estimated to cost $60,000. It will be six stories in height, and will contain one hundred beds, one for each nation represented in the Red Cross. The training-school will be four stories high, and both it and the hospital will be fitted with every modern appliance.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending February 16, 1901. February 7th.—Passed Assistant Surgeon C. P. Bagg detached from Cavite naval station and ordered to the *Culgoa*. Passed Assistant Surgeon A. R. Alfred detached from the *Culgoa* and ordered to the naval station, Cavite. February 9th.—Surgeon C. Biddle detached from the naval hospital, Norfolk, Va., and ordered home to wait orders. February 13th.—Surgeon D. O. Lewis detached from the *Iowa* and ordered to the *Philadelphia*. Surgeon W. E. Arnold detached from the naval recruiting rendezvous, Chicago, Ill., March 1st, and ordered to the *New Orleans*, sailing March 15th. Surgeon S. H. Griffith detached from the *Prairie* when put out of commission, and ordered to special duty under the Bureau of Medicine and Surgery. Surgeon F. J. B. Cordeiro detached from the *New Orleans* on reporting of relief, and home to wait orders. Surgeon A. M. Moore, retired, ordered to duty at the naval recruiting rendezvous, Chicago, Ill., March 1st.

Quaker Longevity.—In a highly interesting communication to the London *Times*, a correspondent calls attention to the uncommon longevity of members of the Society of Friends. He says: "During the year ending in 1900, there were reported the deaths of 299 members of the Society of Friends in Great Britain and Ireland. The proportions were 159 males and 140 females. The average age at death was a little over sixty-one years and seven months. A table compiled from the returns shows that there is a very limited mortality of children, and that it is chiefly in this respect that the death rate of the Society of Friends differs from that of the general population. Only 14 deaths out of the 299 were reported as those of children under five years of age; between five years and twenty years the number was 9; between twenty and thirty years the deaths were 16, and the same number was that of the deaths between thirty and forty years. From forty to fifty there were 24 deaths, and from sixty to seventy there were 62 deaths. From seventy to eighty the number was 57 and from eighty to ninety, 69. There were 8 deaths of Friends between ninety and one hundred years of age, and there were 2 deaths of persons over one hundred. One of the latter died at Croydon in her one hundred and first year, and others had passed one hundred and one years of age."

Dr. Daniel W. Marston has been appointed visiting surgeon to the Randall's Island Hospital, by the department of public charities.

Police Surgeon Retired.—The police board has just retired Dr. Benjamin F. Dexter, who is sixty-eight years old, and has been a police surgeon since 1876.

Plague Cases at Manila.—A special despatch to *The Sun*, February 11th, reports that three cases of plague and seven cases of smallpox were discovered in Manila last week. The appearance of these diseases causes no alarm to the health board, which is prepared to control their annual visitation, usually expected during the hot season.

Smallpox at Poughkeepsie.—It is reported that two cases of smallpox have been discovered in Callahan's Hotel at Fishkill Landing, Poughkeepsie. The victims are employees of the New York, New Haven and Hartford Railway. The place has been quarantined. The men are said to have been under treatment for measles for two weeks before the character of the illness was determined. There has been a general rush for vaccination by citizens.

Conduct of Civil Surgeons in South Africa.—The report of the British Royal Commission on army medical arrangements in South Africa says: "The civil surgeons employed in this campaign have, as a body, done their duty extremely well. But few complaints have been made against any of them, and such complaints as have been made are not of a grave character. As a rule, the civil surgeons worked well with the officers of the Royal Army Medical Corps. A few cases of friction occurred between them in certain hospitals. These arose from faults on both sides. Some civil surgeons not unnaturally felt a difficulty at first in becoming acquainted with the working of military hospitals, but as a rule they soon became familiar with their duties."

The Alcohol Habit and the National Woman's Christian Temperance Union.—The National Woman's Christian Temperance Union has been active for twenty-seven years in combating the evils of alcoholic liquor drinking. Among its most effective allies have been those physicians who do not prescribe alcoholic liquors, allowing alcohol a very limited sphere of usefulness or none at all. The Union has endeavored to bring the teachings of such physicians to the people. It is apparent, however, that if the evils of liquor drinking (ill health, poverty, insanity, and crime) are ever to be fully abated, the medical profession must take an active part in this much-desired reform. It,

more than any others, can disabuse the public mind of the old-time errors concerning the too free use of alcohol, either as a beverage or as a self-prescribed medicine.

Obituary Notes.—Dr. Peter Moir Barclay, a leading physician of Orange County, N. Y., died in Newburg Monday night, February 11th. He was born in Aberdeen, Scotland, in 1834, and was graduated from the medical department of the University of the City of New York in 1854. He was surgeon of the Nineteenth Regiment, New York Infantry, with the rank of captain, from 1866 until the regiment was disbanded.

Dr. Samuel C. Busey, a prominent physician of Washington, D. C., died February 12th. He had been in feeble health for several years, and had practically retired from the practice of medicine. He was identified with numerous scientific and historical societies, and contributed extensively to medical literature. He was born in Montgomery County, Md., seventy-two years ago.

Dr. E. S. Miller died at Altoona, Pa., on February 10th, at the age of forty-five years. He was a graduate of the medical department of the University of Pennsylvania.

Dr. N. B. Boileau died suddenly at Jutland, N. J., on February 12th, at the age of sixty-eight years. He was graduated from the medical department of the University of Pennsylvania in 1858.

Dr. John M. Drurro died at Wilkesbarre, Pa., on February 14th, from an attack of influenza.

Dr. Horace G. Hill, of Philadelphia, died on February 14th, at the age of forty-two years. He was a graduate of Williams College and of Jefferson Medical College.

Dr. William Rice died at Trenton, N. J., on February 13th, at the age of sixty-three years. He was mayor of Trenton in 1879 and 1880.

Dr. William Meadows Rose died on February 10th, at his residence, 8 Brewster Street, Tompkinsville.

Dr. Frank Bond died on Sunday, January 10th, at his home, 27 Schermerhorn Street, Brooklyn, in his seventy-third year. The cause of death was pneumonia. He was a graduate of Williams College and of the Medical College of Iowa. He had been in practice in Brooklyn for thirty-six years.

Dr. Walter Myers, B.Sc. Lond., M.B. Camb., who had been engaged at Para in Brazil in investigating the cause of yellow fever for the Liverpool School of Tropical Medicine, died recently.

Dr. J. H. Linsley, founder and director of the Vermont State Laboratory of Hygiene, died of cerebral meningitis at Burlington, Vt., aged forty-two years. He was educated in the public schools of his native village, Windsor, and graduated from the medical department of the University of Vermont in 1880. In 1887 he was appointed instructor in clinical microscopy in the New York Post-Graduate Medical School, and in addition did the bacteriological work for St. Luke's Hospital of New York. He twice visited Germany for bacteriological study, and ranked deservedly high in that special line of work. He was, during his residence in New York, an active member of the New York Pathological Society, of the Medical Society of the County of New York, and later became the representative bacteriologist of his State. A widow and two children survive him.

Dr. Homer O. Jewett died at Cortland, N. Y., January 29th, aged about eighty-two years. He was graduated from the University of the City of New York in 1842, and had been engaged in the practice of his profession until about three years before his decease.

Dr. Richard S. Seaman died on February 17th in Brooklyn, in his seventieth year. He was the last surviving member of the Delta Chapter of the New York University of the class of 1845. He was descended from Capt. John Seaman, who held the patent to the town of Hempstead, L. I., about the middle of the seventeenth century. Dr. Seaman had practised for over thirty years at Glencove, L. I. He leaves three sons and two daughters.

Progress of Medical Science.

New York Medical Journal, February 16, 1901.

Stethophonometry.—By Albert Abrams. The author notes that under certain clinical conditions auscultation is no trustworthy index to the force of the heart. Instruments designed to gauge the pulse are unreliable in that we must contend with the objectionable personal equation and content ourselves with the determination of the blood pressure in the systemic circulation only. The aim is to determine the exact force of the heart impulse as measured by the heart tones, but for this purpose the ordinary stethoscope will not answer. To meet this need the author has devised an instrument which he calls a "stethophonometer," which is thus described: It is constructed on the disc-valve principle, weighs about two ounces, and is composed wholly of hard-rubber. There are three perforated discs in close apposition, the middle disc being made to revolve by means of a handle attachment so that its opening may be made to approach or recede from the opening in the two other discs. The greater the encroachment on the opening by the middle disc, the greater will be the resistance offered to the transmission of the sound waves. On the face of the disc nearest the auscultator is a scale by which the intensity of the chest sounds may be measured. On one side of the discs the bell of the stethoscope is affixed, and, on the other side, a plug, the size of which may be varied to fit any stethoscope. This plug is perforated, and in the perforation may be fitted a rubber cork, if necessary, to offer still further resistance to sound. The latter expedient, however, is rarely necessary. The stethophonometric attachment can easily be removed when it is found necessary to carry out the conventional method of auscultation.

Combined Surgical Operations in Female Subjects at a Single Seance.—By R. S. Sutton. Years ago, says the author, it was customary, when a female patient presented herself with lacerations of the cervix and perineum, to repair the former first and then to wait a while before repairing the latter. The consequence was that, in case there were several abnormalities requiring attention, the patient was confined a long time to bed. The experience of recent years has shown that if aseptic methods and reasonable speed in operating are followed, it is possible to combine several operations at one sitting. It is a fact gained by experience that, in a patient in fairly good condition, a long wound will heal with about as much safety and expedition as a short one, provided asepsis has been maintained with reference to both wounds. A multiplicity of short wounds is equivalent to a long wound, provided they involve similar tissues, but in multiple operations dissimilar tissues are involved. Yet it has been found that the long wound composed of dissimilar tissues heals quite as readily. Sutton gives a summary of the histories of fifteen cases illustrating modern views as to combining operations. Thus, in one case, the following operations were done at the same séance: Curettage, trachelorrhaphy, perineorrhaphy, divulsion of sphincter ani muscle, laparotomy with removal of appendages, and anterior fixation of fundus. Time, forty-five minutes; result, recovery.

A Study of Buboes and their Treatment.—By F. Griffiths. Pathology and diagnosis are discussed at some length, and treatment is then considered. Special attention must be paid to the chancroid. For cleansing, the author recommends peroxide of hydrogen, followed by the use of black wash. As soon as a bubo has formed, applications should be made of icebags or hot fomentations in an endeavor to abort pus formation. Applications are recommended of equal parts of the ointments of mercury, belladonna, and ichthyol. If pus forms, the bubo is to be punctured with a small blade, and a blunt probe or grooved director swept around the cavity and through the honeycombed tissues, thus opening up channels of exit. In cases in which puncture is made for relief of pain, and the infected gland will not discharge, five or ten drops of pure carbolic acid are to be injected through a hypodermic syringe into the centre of the hardened tissue. Should the action be too great, alcohol (ninety-five per cent.) may be used to neutralize the effect of the acid. Under this plan, the author claims that it is not necessary to confine patients to bed. Results are prompt and permanent.

Septicæmia in Young Chickens.—By L. F. Rettger. The article is a continuation of previous studies on the same subject.

The Normal Declinations of the Retinal Meridians.—By G. T. Stevens. A continued article.

Hysterical Anæsthesia and Analgæsia.—Report of a case by B. C. Loveland.

A New Portable and Inexpensive Ophthalmometer.—By W. F. Aiken.

Journal of the American Medical Ass'n, Feb. 16, 1901.

The Etiology of Yellow Fever.—Walter Reed, James Carroll, and Aristides Agramonte offer the following conclusions: (1) The mosquito—C. fasciatus—serves as the intermediate host for the parasite of yellow fever. (2) Yellow fever is transmitted to the non-immune individual by means of the bite of the mosquito that has previously fed on the blood of those sick with this disease. (3) An interval of about twelve days or more after contamination appears to be necessary before the mosquito is capable of conveying the infection. (4) The bite of the mosquito at an earlier period after contamination does not appear to confer any immunity against a subsequent attack. (5) Yellow fever can also be experimentally produced by the subcutaneous injection of blood taken from the general circulation during the first and second days of this disease. (6) An attack of yellow fever produced by the bite of the mosquito, confers immunity against the subsequent injection of the blood of an individual suffering from the non-experimental form of this disease. (7) The period of incubation in thirteen cases of experimental yellow fever has varied from forty-one hours to five days and seventeen hours. (8) Yellow fever is not conveyed by fomites, and hence disinfection of articles of clothing, bedding, or merchandise, supposedly contaminated by contact with those sick with this disease, is unnecessary. (9) A house may be said to be infected with yellow fever only when there are present within its walls contaminated mosquitos capable of conveying the parasite of this disease. (10) The spread of yellow fever can be most effectually controlled by measures directed to the destruction of mosquitos, and the protection of the sick against the bites of these insects. (11) While the mode of propagation of yellow fever has now been definitely determined, the specific cause of this disease remains to be discovered.

The Major Obstetrical Operations.—Edward Reynolds believes that: (1) When the conditions are such that the child can be delivered with anything like reasonable ease by forceps or version, one of these operations is preferable to any cutting operation. (2) When the mechanical relations would render forceps or version unusually difficult, forcible and prolonged, and when the mother is in the favorable class, the equally low maternal mortality and the far lower fetal mortality of the Cæsarean section render it the operation of choice. (3) When the mechanical conditions make the intrapelvic delivery of an intact child at term, impossible or unduly difficult, the great superiority of the Cæsarean section over the induction of premature labor in fetal mortality, and its extremely low maternal mortality, render it again the preferable operation. (4) When the ordinary operations fail, and the woman is in the unfavorable class, symphysiotomy is the operation of choice, and may be expected to lead to a favorable result for both mother and child, in the great majority of cases, provided always that the degree of mechanical difficulty permits of its application. (5) When in the unfavorable class of cases, the degree of relative disproportion between head and pelvis is too great to admit of a safe symphysiotomy, craniotomy to the living child should be unhesitatingly chosen, since the maternal mortality of either form of the section is so enormous, and since undoubtedly the life of the potential mother of many children is of more value than that of any unborn fœtus.

Possibilities of Liquid Air to the Physician.—A. Campbell White states that liquid air applied to the healthy living tissues causes a temporary local anæmia accompanied by anæsthesia, or a slough, depending upon the amount used. In many cases this anæsthesia is preferable to any other, *e.g.*, in the opening of an abscess where there is always an element of some danger in the use of cocaine. It is ideal as a cold application to allay or abort an acute inflammation. It is successful in the treatment of lupus. It is of great utility in the treatment of chronic ulcers, as a stimulant. It is an excellent cauterizer. In cancer it has done great good in the relief of pain and in the destruction of bad odor.

Boston Medical and Surgical Journal, Feb. 14, 1901.

A Case of Complete Placenta Prævia.—Frederick Coggeshall reports a case in which the patient was apparently in extremis. He at once started the subcutaneous injection of decinormal salt solution under both breasts and underneath the loose skin of the back, at the same time, by means of a three-way tube. The foot of the bed was raised, and a gr. $\frac{1}{10}$ strychnine nitrate was given subcutaneously. Version and delivery were rapidly accomplished. The patient had stopped breathing, and artificial respiration, including the Laborde method, was applied. The uterus received a hot douche of 1:1,000 bichloride solution as soon as it was empty, and was packed with gauze on which had been emptied a two-ounce bottle of liqor ferri chloridi. It contracted at once and the hemorrhage was all over in about two minutes. The mother slowly recovered.

Disinfection within or without the Body, in Diphtheria.—M. A. Veeder says that there are three forms of disease formerly confounded as diphtheria, *i.e.*, diphtheroid, characterized by staphylococci mostly; true diphtheria, by the Klebs-Loeffler bacillus; and septicæmic sore throat, by the streptococci. Diphtheroid predisposes to both the other forms. Physicians may be infected without knowing it, and carry infection to other patients. To protect himself, the writer wets his face with a sublimate solution before and after the examination of a case, and holds a square of antiseptic gauze over his mouth and nostrils, with his left hand. This, together with frequent spraying and cleansing of the mouth and throat and nostrils, and bacteriological testing, affords very complete security against either giving or receiving infection.

A Case of Cæsarean Section for Complete Placenta Prævia.—C. H. Hare reports the case of a woman who refused her physician's advice to go to a hospital, until she had lost so much blood from the uterus as to be nearly in collapse. Cæsarean section was done as a choice of evils; the mother died eleven hours after the operation, and the child lived thirteen days. The author believes that, in most cases of placenta prævia, Cæsarean section is fully as safe for the mother as delivery by the older methods, and that it will save far more babies. For cases where the mother is already collapsed from loss of blood, the statistics are certainly not good.

The Woollen-Yarn Truss in Infantile Inguinal Hernia.—E. S. Boland says that (1) the use of some retentive apparatus will hasten and assure the natural tendency toward cure in infantile hernia; (2) the worsted-yarn truss is easily made to measure, at the bedside; it is cheap, comfortable, and can be worn by frail or delicate infants, for whom the ordinary truss is useless or too irritating; (3) with this or any other truss, vigilance and intelligence must counteract the underlying or associated causes of the hernia.

A Case of Idiopathic Dilatation of the Colon.—Maurice H. Richardson reports a case in which extensive resections brought relief for some months. The dilatation then returned. In another operation the presenting coil was reduced by numerous transverse infoldings, but the tumor remained, and the pain and the discomfort persisted. In a third operation the dilated bowel was completely excised. The latest report is that the patient's general condition is good, but the local trouble has returned, and there is severe abdominal pain.

Philadelphia Medical Journal, February 16, 1901.

Periodical Insanity.—A. R. Defendorf presents the following conclusions on this subject: (1) Periodical insanity is a mental disease characterized by a definite symptomatology, course, and outcome. (2) In point of numbers, it is one of the most prominent psychoses. (3) The symptoms are sufficiently characterized to permit a differentiation, in the first attack, from other forms of mental disease, (4) and allow the forecast of the whole course of the disease, *i.e.*, (5) recurrence of attacks throughout the life of the individual, mostly of the character of the first, (6) with lucid intervals of varying length from weeks to years, except in a very small percentage of cases, (7) without a tendency to mental deterioration, except in cases in which the attacks have been long, frequent, and severe, and even then the deterioration is of a light grade.

The Treatment of Erysipelas.—N. G. Keirle, Jr., reports this treatment which has met with great success in his hands: The affected area is first enclosed in a painted ring of tincture of iodine. This ring is not to be started at the margin of the reddened area, but from two to three inches from it, and enough coats should be given to cause a slight desquamation of the upper layers of the skin. The whole surface within the ring is to be covered with ichthyol ointment, about 1 drachm to 1 to 2 ounces of vaseline. This is covered with a piece of gauze and a hot stupe applied and changed about every four hours. At the end of twelve hours the ointment is washed off and a fresh coat applied. If necessary, more iodine may be used. Internal treatment may or may not be given.

Perforating Ulcer of the Stomach; Operation; Recovery.—By John H. Musser and Henry R. Wharton.

Medical News, February 16, 1901.

A Hair-Cast of the Stomach; its Successful Removal by Laparotomy.—Nathan Jacobson reports this case of a girl aged eleven years. One year before the child was referred to the writer, a swelling was noticed in the abdomen. She vomited a great deal of frothy mucus. Later she began to suffer from colicky pains, which were frequently relieved by friction or medicine. She suffered especially at night. Most of the pain was located to the left of the umbilicus. Her bowels had been constipated for a year. Ordinary food was so disturbing that she lived chiefly on milk. She was quite nervous. The urine was normal. As a rule, the temperature remained normal. As a diagnosis could not be agreed upon, laparotomy was performed and the tumor mass found to consist of black hair. After the operation the patient admitted that from her earliest years she had bitten off the ends of her hair. The tumor is a perfect cast of the stomach in a state of contraction. It is six inches in its long diameter.

Treatment of Lupus.—H. Rockwell Varney states that in the treatment of cutaneous tuberculosis there has as yet been no specific serum discovered that can neutralize the virus and produce absorption of the tubercle. External treatment may be divided into surgical and mechanical. Excision has been used with good results. The writer has had success in the use of the curette. When cases are new and not broken down, linear scarification may be used. Electrolysis is advocated by some, especially in recurrent lesions. Mechanical treatment consists in the use of escharotics and caustic pastes, which will most rapidly destroy the tubercle. Nitrate of silver stands first. Arsenical pastes are more rapid in their action, but they cannot be used on large areas because of absorption. Acids have been used. The writer then praises the *x*-ray treatment. It is painless and has given good results.

A Nail Embedded in the Right Bronchus for Two Months; Diagnosis by Radiography; Removal by the Electro-Magnet; Cure.—J. Garel reports the case of a child aged eighteen months, who had swallowed a nail. It was two months later when the writer was consulted. Before seeing the patient, the writer, after hearing the history of the case, thought that it was possible that the nail had passed the larynx and trachea and had lodged in the right bronchus. The persistent cough, he considered, might well be provoked by the permanent irritation of the bronchus by a foreign body. He suggested a radiograph in order to obtain the diagnosis. This measure accordingly was undertaken, the result showing a long nail lying obliquely in the thorax, in the direction of the right bronchus, the point below and the head above. The child was etherized and tracheotomy performed. The cannula was introduced and the child respired normally. As the child made no effort to expel the nail, and an attempt to extract it could not well be made with the cannula in place, it was withdrawn and another instrument with two branches substituted, which made intervention easier. Before making use of the forceps to remove the nail, an electro-magnet was brought near the open wound, at which the nail quickly jumped from its hiding-place and clung closely to the magnet. The operation was really terminated to the astonishment of all. The cannula was replaced for a few days. The nail was 53 mm. in length. The child made a happy recovery and shows no trace of respiratory or laryngeal trouble, now several months after operation.—*Lyon Médical*, January 6, 1901.

Purpura Hæmorrhagica from Auto-Intoxication.—J. A. Lesage reports a case and then speaks of the three varieties of this affection: (1) Apyretic purpura or sickness of Werlhof. This occurs in apparently perfect health or after an emotion or traumatism which is inconsiderable, and it is attended by no fever. The hemorrhages cease after eight or ten days, and the normal condition returns without the slightest complication. (2) Rheumatoid purpura. This type occurs chiefly in the springtime, in young patients with an arthritic or neuropathic tendency. Sometimes œdema is present. After a time all the troubles disappear without leaving a trace behind. There is fever and the affection lasts for weeks, sometimes for months. (3) Infectious purpura, properly so called. Generally, in spite of complications, the termination is favorable, after a length of time which varies according to the nature of the affection and the gravity of the attack. As to the treatment, it is considered in relation to three principal symptoms which chiefly attract the attention: (1) Hemorrhage, the most alarming symptom, demands complete rest in bed, subcutaneous injection of gelatinized serum, and a gargle of potassium chlorate every half-hour for disinfection of the mouth. (2) In order to combat the infectious pseudo-occlusion of the intestine, calomel and scammony, followed by sulphate of magnesium, are administered. An absolute milk diet is ordered—boiled milk, Vichy, and lime-water. Benzo-naphthol may also be given. (3) For the blood changes, protoxalate of iron and phosphate of sodium are administered.—*L'Union Médicale du Canada*, January, 1901.

Berliner klinische Wochenschrift, No. 3, Jan. 21, 1901.

Affections of the Hip Joint.—Koenig considers two special conditions, gonorrhœal coxitis and coxitis due to arthritis deformans. The first form occurs by preference between the twentieth and the fortieth year. Out of twenty cases studied by him, eleven were in women and nine in men. The affection is more common during the acute stage of the urethritis, but may also occur during the chronic stage. In five instances a trauma of the general hip region preceded the joint symptoms proper. Pregnancy seems to invite the onset of this form of joint affection. Two groups of clinical cases present themselves: first, those with gradual onset of pain and restriction of joint movement. These increase in intensity, the most marked feature being the excruciating pain. The second group commences with severe disturbances of motion, severe pain, and an evident tumor.

A Further Contribution to the Surgery of the Heart: Ligation of the Injured Coronary Artery.—Pagenstecher reports a highly interesting case in which ligation of the descending branch of the left coronary artery was performed at a point over two inches from the apex, and though the patient succumbed five days later, the fatal termination was apparently due to complications rather than to any damage to the heart resulting from the interference with its blood supply. The patient had sustained a self-inflicted wound of the pericardium piercing the fourth costal interspace and about three-quarters of an inch long. In view of the rapidly progressing symptoms of collapse and general weakness, two and a half hours after the injury the heart was exposed by the raising of an osteoplastic flap consisting of the sternal ends of the fourth and fifth ribs. The

pericardium was found filled with blood which on the free admission of air was churned into foam which could be removed only with difficulty. The source of the bleeding could then be located as the wounded coronary artery, which was ligated and the operative wound closed except for a small distance at its lower angle to allow the passage of a drain. The patient bore the operation well, but five days later died of sepsis.

A Fatal Case of Scalding of the Pharynx and Larynx.—E. Schmidt reports a case of this injury, which is comparatively frequent in England, where tea-drinking is so widespread a custom, but is said to be very rare in Germany. The patient was a three-year-old child, who received the injury in the usual way by attempting to drink from the spout of a boiling kettle. The most remarkable feature of the case was the slight amount of local damage visible and the absence of general symptoms, for several days after the accident. This was explained by the very deepseatedness of the injury, for at the autopsy it was found that tissue destruction had taken place only within the larynx itself, and at the junction of the pharynx and the œsophagus. One day after the scalding there were present slight dyspnœa and dysphagia and slightly increased respiration, but a few hours later the condition was complicated by the appearance of extensive cutaneous emphysema of the neck. A little later dyspnœa became extreme and was not relieved by tracheotomy, and on the following day death ensued from pneumonia. A review of the literature of such cases justifies the belief that, in spite of the very great risk of pneumonic infection, tracheotomy is nevertheless usually indicated.

A Method for the Simultaneous Staining of Blood Smears with Eosin and Methylene Blue.—E. A. Willebrand describes a new stain which gives more clearly differentiated pictures than Ehrlich's triacid mixture, Gollasch's eosin-hæmatoxylin, etc. If dried blood smears be stained with a simple mixture of eosin and methylene blue the results are unsatisfactory, for one stain usually preponderates over the other according to the proportions of the mixture, and it is difficult to find a formula in which the two stains balance. If acid is added to such a mixture, however, the staining-powers of the eosin are accentuated, while the addition of alkali makes the blue the stronger element, and this fact renders an accurate regulation of the result possible. The author's formula is equal parts of 0.5-per-cent. alcoholic eosin and concentrated watery solution of methylene blue. To 50 c.c. of this mixture ten to fifteen drops of one-per-cent. acetic acid are added (the exact amount being determined by experiment), when the erythrocytes will be found stained red, the nuclei blue, the neutrophile granules violet, the eosinophile granules red, and those of the mast cells an intense blue.

Mastitis Adolescentium.—Richard Adler describes under this term a painful affection of the mammary glands, most often seen about puberty and in both sexes. It is characterized by a slow swelling of one or both glands, which become very sensitive to the touch and slightly reddened. Frequently a drop of clear fluid may be expressed, but, contrary to the writings of some authors, suppuration never occurs. Adler agrees with Langer in considering the process one of true physiological hypertrophy and not of inflammatory nature. The therapy consists mainly in the application of placebos, for which iodine and blue ointment are suitable, and the guarding of the affected part against irritation, by the use of some protective dressing. In extreme cases extirpation of the gland may have to be resorted to, in which case the nipple should always be left intact for cosmetic reasons.

Basophile Granulations in the Red Blood Cells.—O. Moritz says that while some authorities maintain that the presence of basophilic degeneration of the erythrocytes is of true diagnostic value, others explain the manifestation as due to artefacts or post-mortem changes. In order to test the significance of the phenomenon in lead poisoning he gave rabbits small amounts of lead acetate with the result that in a few days the granulations were always to be found. This experimental evidence is further corroborated by the finding of typical granules in the blood of six workmen employed in a lead factory, although only one gave symptoms of intoxication at the time of examination. The conclusion is that the finding of such degenerated cells is diagnostic of lead poisoning, though they have also been found in five other cases, viz., in two of leukæmia, in malaria, sepsis, and carcinosis.

Clitoris Crisis.—G. Köster describes a tabetic manifestation in women, which is occasionally to be found mentioned in the literature of the disease, but so sparingly as to attest its rarity. The case reported, which, in addition to the condition about to be described, was interesting in also presenting laryngeal crises, obstinate erythromelalgia, and fragilitas ossium, was that of a woman aged forty-nine years. The first symptoms of tabes were observed in 1880, and six years later the ataxia had progressed so far that locomotion was possible only by daylight and with the aid of a cane. Since 1890 the patient experiences every four weeks, at about the time of the menstrual period, a peculiar access of sexual feeling which comes on wholly independently of her volition or desire, and usually appears at night when she is awake or only half asleep in bed. A sensation of pleasurable tickling begins in the vagina, travels down to the clitoris and vulva, and finally culminates in a true orgasm of erotic feeling. All efforts of the patient are powerless to prevent this result, and immediately after the voluptuous sensation ceases sharp, darting pains, originating in the vagina and uterus and shooting into the back, set in and last for several hours. At the same time attacks of the ordinary lancinating pains in the extremities frequently come on.

The Diagnosis and Prognosis of Gonorrhœa in Men.—A. Köppen cites two cases which emphasize the fact that in this disease certainty in diagnosis can be reached only through bacteriological examination of the discharge. A young man presented himself, suffering from a urethral discharge which, from the history and the patient's general character, seemed almost as a foregone conclusion to be gonorrhœal. The microscope did not reveal gonococci, however, and further search brought the real cause of the trouble, the tubercle bacillus, to light. The clinical diagnosis of genito-urinary tuberculosis was corroborated by the course of the disease, which finally terminated abruptly in an acute general miliary process. In the other case the patient's age, sixty years, and other considerations seemed to justify the assumption that his discharge was tuberculous, but on investigation gonococci were found in abundance.

A Case of Acute Leukæmia Without Macroscopic Pathological Changes in the Blood-Forming Organs.—A. Dennig reports the case of a young woman who came under observation with the subjective symptoms and history of chlorosis, but did not improve under the treatment appropriate to this condition. A blood count was then made, which revealed only 800,000 red cells to the cubic millimetre, and the leucocytes in a ratio of 1 : 40 to the red cells. A few normoblasts were present and the leucocytosis was composed mainly of large and small lymphocytes. Under rapidly progressive symptoms of general somatic deterioration the patient died a month later, having had retinal and gingival hemorrhages several days previously, and bleeding from the intestine on the day of death. On autopsy it was found that there was no enlargement of the spleen or lymph glands, and that the bone marrow, which before has always been found altered, was macroscopically wholly unchanged.

The Disinfecting Properties of Alcohol and Alcohol Vapor.—G. Frank is of the opinion that the modern tendency to ascribe to this agent only a secondary rôle in the various disinfecting procedures in vogue is not borne out by the facts, and his experiments with anthrax spores seem to justify his views. These very resistant organisms perish in a few minutes after exposure to alcohol or its vapor, and it is worthy of note that the intensity of action is not dependent on the concentration of the chemical. Most micro-organisms are surrounded by an envelope which, on contact with the strongly hygroscopic absolute alcohol, loses water and shrivelling up becomes more resistant, while if a certain amount of water is present this action does not take place, and the disinfectant more easily gains access to the germ within and its destruction is assured.

The Opening of Perityphitic Abscesses in Douglas' Sac by Parasacral Section.—K. Port warmly advocates a somewhat difficult technique for the drainage of appendicular accumulations which have gravitated into the recto-vesical pouch. The incision encircles the anus and is then carried upward along the side of the sacrum. After the pelvic fascia is reached it is possible to approach the mass by blunt dissection through the loose cellular tissue, and the abscess once opened drains completely and freely. The advantages claimed are the freedom from risk of infection, which is great if the operation be done through the rectum as has

been advised, and the perfect drainage secured by the very free incision.

A Case of Ischiopagus.—By L. Sternberg. **Dystocia through a Double Monster.**—By A. Palmedo. Almost similar monstrosities are reported by these two authors. In the first both bodies were joined at the pelvis, two legs being perfectly formed, while a third, springing from the sacrum, was very rudimentary. The heads and four upper extremities were separate and normally developed. In the second case the union was apparently not a true fusion, for the connecting segment between the two thoraces admitted free motion. In both instances delivery was effected without great difficulty, the advancing head being extracted with forceps and the hand then introduced into the uterus and version performed. Both mothers recovered fully.

The Effect of High Temperature on the Casein of Milk.—H. Conradi publishes some experiments which lead to conclusions not differing markedly from what has already been known. Heating milk above a temperature of 80° C. lowers its coagulating point in the presence of calcium salts 8° to 12° C., while its susceptibility to the lab ferment is lessened. Heating to temperatures below 70° C. for half an hour does not change the coagulating characteristics appreciably.

Rivista Critica di Clinica Medica, Jan. 12 and 19, 1901.

The Bacteriology of Typhus Levis.—M. Biffi and P. Galli state that the diagnosis of typhus levis is to be based upon the presence of Eberth's bacillus in the spleen and Widal's reaction, or upon Widal's reaction and the existence of an epidemic of typhoid. The authors emphasize the fact that a case of slight gravity is as likely to carry infection as a severe one, and urge the necessity for sanitary precautions and great vigilance in these cases. They also describe a simple instrument which they have devised and use for determining Widal's reaction.

The Bacteriological Study of Some of the Complications of Influenza.—Aldo and Castellani assert as the result of their researches: (1) That Pfeiffer's bacillus, while it is capable of directly causing the complications of influenza, does not as a rule penetrate to the circulation and give rise to secondary localizations. (2) Many of the complications of influenza are due to secondary infection, and in these Fraenkel's diplococcus plays a great part.

Bulletin of the Johns Hopkins Hospital, January, 1901.

The Removal of Pelvic Inflammatory Masses by the Abdomen after Bisection of the Uterus.—Howard A. Kelly recapitulates the advantages of a bisection and enucleation of the uterus as a preliminary to a complete enucleation of uterine tubes and ovaries for pelvic inflammatory and other diseases by the abdominal route: (1) Additional space for handling adherent adnexa, afforded by the removal of the uterus. (2) Great increase in facility for dealing with intestinal complications. (3) Better access by new avenues from below and in front to adherent lateral structures. (4) Elevation of structures to or above the pelvic brim or even out into the abdomen, bringing them within easy reach of manipulation and dissection. (5) The same advantage in approaching both uterine vessels by cutting from the cervix out toward the broad ligaments as is secured in approaching one of them in the continuous transverse incision method. In general, the time of operation is shortened; its steps are conducted with greater precision; surrounding structures are far less liable to be injured. In this way there are fewer troubles and sequelæ and the mortality is lessened. The writer believes that in intraligamentary tumors of both sides this procedure will prove of the utmost advantage in exposing the tumors at a point low down in the loose cellular tissue of the broad ligament.

The Intrinsic Blood-Vessels of the Kidney and their Significance in Nephrotomy.—Max Brödel concludes his excellent article by describing the method of suturing an incised kidney: (1) The pelvis is approximated with fine catgut sutures. These ought to be placed between the calices and take in only the fat, the outer fibrous coat, and the muscular layers. The mucous membrane should not be included. (2) The second system of sutures should also be of catgut and should unite the region of the papillæ. They should be mattress sutures and are best placed by means of a long straight three-cornered needle with a blunt point, so that no injury to the large vessels results. A possible oozing would only serve to tighten the grip of these sutures and thus to render them more effective. (3) The third system of catgut sutures should also be mattress sutures and should be placed parallel to the second, through the cortex near the bases of the pyramids. Occasionally the third system of sutures is superfluous. (4) The capsule is then closed in the usual manner.

Abstract: The Bacteriology of Cystitis, Pyelitis, and Pyelonephritis in Women.—By Thomas R. Brown.

Notes on Aerobic Spore-Bearing Bacilli.—By W. W. Ford.

The Cleveland Medical Gazette, February, 1901.

Acute Nephritis; Symptomatology.—Orin E. George says that an attack begins in one of two general types. The one is ushered in by a chill, severe pain in the back, pain in the course of the ureter with retraction of the testicle. The nervous phenomena present are severe headache, delirium, convulsions, sometimes blindness in one or both eyes, and coma. In the second type, the attack comes on slowly, beginning with slight headache, nausea, vomiting, white-coated tongue, loss of appetite, malaise, dark spots before the eyes, occasionally pain in the loins, and constipation; sometimes diarrhœa, increase in pulse rate and tension, œdema of lower eyelids gradually extending to all parts of the body. In some cases the acute symptoms persist when the nephritis may pass to a chronic form.

Laboratory Diagnosis of Nephritis.—Martin Friedrich says that all three tests for albumin, namely, heat, nitric acid, and acetic acid plus ferrocyanide of potassium, have to be employed in every case in order to avoid errors. The most important factors, after albumin, are casts. They are subdivided into blood casts, epithelial, granular, waxy, and hyaline. The author gives the significance of each, and full directions for the diagnosis of parenchymatous nephritis. All the morbid changes of the urine taken together, viz., turbidity, less amount with higher specific gravity than normal, the presence of a rather high percentage of albumin, with red blood corpuscles, epithelial cells, and casts in the sediment, are pathognomonic of parenchymatous nephritis, and we can safely say, of an acute attack.

Nephritis, Treatment.—John Perrier says that two important points should be kept in view, viz., the relief of the vascular engorgement of the kidneys, and the elimination of the toxins retained in the blood as a consequence of interference with the renal function. The patient should be put to bed between woollen blankets, given hot drinks freely, the bowels moved with saline cathartics in hot concentrated solutions, and a light diet given, mainly composed of bland nutritious liquids. In severe cases a hot-air bath should be given under the bed clothing. If the urine is scanty or suppressed, a linseed-meal poultices with a tablespoonful of mustard should be applied over the loins, and changed every four hours. In the uræmia of acute nephritis, resort should be had to the subcutaneous injection of normal salt solution.

Acute Hemorrhagic Nephritis in Children.—Edward Perkins Carter says that it is extremely difficult to account for the occurrence of this disease here, or for its absence there. In every case there is present anatomically more or less degeneration of the renal epithelium, and the hemorrhage is found chiefly in the capsules or the glomeruli, in the tubules and beneath the capsule. The fact of its occurrence associated with parenchymatous hemorrhages elsewhere suggests some close affiliation with purpuric processes generally; but when of infective origin, whether it depends upon some peculiar susceptibility of the blood-vessel walls, or is due to the character, virulence, or duration of the infecting toxin circulating in the blood, remains an open question.

Acute Alcoholic Nephritis.—H. B. Ormsby prefers to call this subject acute exacerbation of chronic alcoholic nephritis, for he believes that a true acute nephritis following an alcoholic debauch in previously normal kidneys is extremely rare, if ever found at all. Acute alcoholic nephritis itself is very much overlooked by physicians, on account of the many constitutional symptoms of acute alcoholism, such as cerebral congestion, cardiac failure, gastritis, etc. We have many deaths from apparent acute alcoholism; cases in which, were the patient put to bed and his urine examined, such measures as active purgation, diuresis, diaphoresis, and active cupping might result in saving life.

Acute Nephritis from Chemical Toxic Agents.—John G. Spenzer says that practically the following poisons alone are of importance: sulphuric and oxalic acids in large doses; inhalations of ether and chloroform; poisoning with mercury, glycerin, turpentine, copaiba, sandal, cubebs, etc.; the internal administration of creosote, salicylic acid, sulfonal, trional, tetronal, nitrate of potassium, and urotropin will probably be in evidence before long; externally applied antiseptics, as carbolic acid and iodoform; or local irritants, such as vesicants or ointments containing croton oil, volatile oil of mustard, tar, naphthol, or the like.

The Treatment of Nausea and Vomiting following Anæsthesia after Abdominal Operations.—Hunter Robb says that during the first six to twelve hours the administration of toast water or hot water, one to ten teaspoonfuls every twenty minutes, is comforting to the patient and relieves the thirst sometimes complained of. If vomiting continues after the third day, the possibility of a peritonitis should be borne in mind. Persistent nausea can sometimes be relieved by two or three tablespoonfuls of very hot water containing ten grains of sodium bicarbonate. Washing out the stomach may be necessary.

Nephritis, Progress.—F. A. Payne says that the tendency in acute Bright's disease is toward recovery. Complete recovery is the rule in acute cases accompanying diphtheria, typhoid, and other infectious fevers, except scarlatina, in which the prognosis is not so good. In acute productive or diffuse nephritis many of the cases end unfavorably. A fatal termination of this disease is indicated by a very scanty flow of urine, frequent and distressing vomiting, extreme anasarca, severe and persistent headache, convulsions, coma, and the occurrence of complications.

Nephritis, Diagnosis.—A. J. Skeel gives detailed directions for the diagnosis of this disease. The obtaining of an accurate history of the case is of considerable importance. In a patient presenting such a typical combination of symptoms as headache, backache, nausea and vomiting, muscular twitchings, pallor of the skin, and œdema of the eyelids and extremities, all coming on rapidly, a urinary examination will suffice to make the diagnosis certain.

Acute Syphilitic Nephritis.—Charles J. Aldrich reports two cases. The disease is always serious, however mild the syphilitic infection. The author, after considerable examination of the literature, is convinced that but few of these cases are fatal. The treatment should be that of acute nephritis from any cause, to which is added a vigorous but judicious course of specific treatment with mercury.

The Sanitary School-Room.—L. K. Baker describes the location of the ideal school-room, its dimensions, walls, contents, and the cloak-rooms. He suggests that each medical man, as he may find time to consider this matter, compare the school-rooms of his acquaintance with the suggestions in this article.

The Edinburgh Medical Journal, February, 1901.

On Bad Positions of the Pelvis, Productive of Spinal Curvature.—Richard Barwell says that the pelvic malpostures with which we have to do are three in number: pelvic obliquity, in which one side of the pelvis lies higher than the other, and which is dependent on a difference in the length of the lower limbs; amesiality of the pelvis, a term indicating that the patient in standing erect habitually places the pelvis to one side of what should be the central mesial line of his figure; and version of the pelvis. The author gives directions for ascertaining these malpostures by means of the camera or of a tape. He says that while he will not affirm that no spine standing on a straight pelvis is ever affected with lateral deviation and rotation, yet it may be written with certainty that since he detected two malpostures of the pelvis about thirty years ago, he has seen no case of scoliosis in which, either while standing, sitting, or both, the pelvis was normally and properly placed. The object of his article is largely prophylactic.

The Borderland.—G. W. Balfour, in a second lecture on the subject, discusses choreomania, table turning, thought reading, mesmeric mania, spiritism, etc. One lesson to be learned, he says, is that insanity is a disease of which no one need be ashamed, as some of the finest minds in all ages have suffered from it. The second lesson is that, as the great object of all education is to enable us to control the emotions and passions, and to regulate the imagination by the cultivation of the faculties of judgment, comparison, and attention; and as whatever tends to emancipate the lower powers of our nature from the wholesome control of our judgment and our will is injurious to our intellectual well-being—we ought to shun all forms of mental excitement, under whatever names they present themselves, which tend to enfeeble our will, or to rouse the emotions and kindle the passions at the expense of those powers which have been given us for their regulation and control. He is assured that no form of even a minor mania has ever passed over the surface of society without leaving behind it many sad traces of its injurious action.

The Bacterial Treatment of London Crude Sewage at Barking and Crossness.—A. C. Houston describes at length the investigations made by him, which occupied two years. His general conclusions are that when an effluent is turned into a stream to be used for drinking-purposes, the bacteriological results are manifestly of more importance than the chemical; but when, as in the present case, the river is not a potable one, and is already polluted, the converse probably holds good. In the first case the chief object is to guard against disease, and in the second case the main consideration is to avoid fouling the river with putrescible matters to such an extent as to constitute a grave public nuisance.

Cholesteatoma of the Temporal Bone and its Treatment.—H. J. Waring reports two cases. He defines the affection as a tumor composed of a large mass of epithelial cells, squamous in character. The swelling is localized and usually has the form of an oval-shaped growth situated in the interior of the temporal bone, in connection with either the mastoid cells, or the mastoid antrum, or the tympanic attic. He has had good results from operation. The chief difficulty is rendering the cavity aseptic after the tumor formation has been removed. He uses irrigation with a solution of bichloride of mercury, but thinks that a solution of formalin is perhaps better, the active antiseptic being volatile.

On Intra-Peritoneal Rupture of Simple Ovarian Cysts, with Special Reference to Operative Treatment.—F. W. N. Haultain reports three cases in which the cyst wall was torn and the contents were evacuated into the peritoneal cavity, and three others in which a distinct history of previous rupture was elicited. He believes that ruptured cysts should in all cases be removed as soon as possible.

Medico-Legal Notes.—Harvey Littlejohn reports a case of extensive atelectasis of the lungs, in a child which lived twenty-four hours, and also a case of finger-nail abrasions on the neck of a newly born child, with reasoning to prove that the latter were probably the result of homicidal strangulation rather than of an attempt at self-delivery.

The Scottish Medical and Surgical Journal, Feb., 1901.

The Relation of Dentistry to Medical Education.—W. H. Williamson, president of the Aberdeen Medico-Chirurgical Society, urges physicians to acquire more dental knowledge than they at present possess, the mouth being so important a part of the body in regard to the general health, both as to the use of the organs of mastication, and because it is so fine an incubating-box for hosts of bacteria, pathogenic and non-pathogenic, aerobic and non-aerobic, the last-named being found in the deeper layers of carious dentine. The author instances cases of mistakes on the part of practising physicians, who in seeking the cause of facial neuralgia either neglected an examination of the teeth, or if they made it, did not recognize existing conditions. Many young practitioners scarcely know how to answer the questions of young mothers in regard to their infant's first and second dentition.

Eclampsia at the Sixth Month; Recovery; Successful Labor at Full Time.—Michael Dewar reports a case which he decides was eclampsia, although there was no albuminuria during a first series of convulsions, only a trace in a second, and none during a third. Epilepsy he excludes for sufficient reasons. He believes that in cases of this nature, chloroform is injurious, as is morphine, and that a little more of the expectant treatment, after attending to the bowels and bladder, with the administration of the bromides and chloral, is perhaps the best method. If there be no signs of nature having commenced premature labor, he would wait for a day or two at any rate before practising fœticide, but if the os is opening up, and uterine contraction taking place, the sooner the uterus is emptied the better.

A Curious Case of Disordered Cerebral Circulation.—Philip G. Borrowman reports the case of a boy aged nine years, who in playing with other boys used to stand on his head, being held by the legs, and who outdid the other boys in this performance. The result was an illness marked by headache at first, then continuous sleep. Tincture of digitalis, ♏ x. three times a day, brought about recovery. The author considers that all the symptoms can be accounted for on the theory of passive congestion. The prolonged inversion of the boy's body would throw the weight of a column of blood, equal practically to the boy's height, on the cerebral veins, causing great engorgement, which of course would cause compression of the brain substance and capillaries, with the result that the arterial circulation would be impeded, and a condition of practical anæmia of the brain induced.

A Short Note on Bilharzia Hæmatobia.—David Wallace gives three cases of this affection, which is due to a para-

site which belongs to the nematode group of worms. Its habitat in the human subject is chiefly the portal vein and its branches, but it is found in other veins, notably the vesical. The ova are mainly found in the urine, but have been found in different tissues, especially in the walls of the bladder and rectum. Hæmaturia is the salient symptom, and the condition is commonly named in South Africa blood-water, or blood-gravel, the sufferers not infrequently passing small calculi. The mode of infection is not known, although some believe that the parasite gains entrance through individuals drinking impure water, or by bathing. Salol has been found of benefit in the treatment.

The Bacillus Coli Communis in Relation to Cystitis.—Kenneth M. Douglas, as a result of experimentation and clinical investigation, concludes that this bacillus is met with in the great bulk of cases of cystitis, and in many is apparently the determining cause of the disease. It is sometimes present during long periods in the bladder, under favoring conditions, but without causing cystitis. Certain of the facts lend support to the view that the bacillus is a supplanter of other forms rather than the initiating cause of the disease. The marked polymorphism and varying pathogenicity of the organism would account for the conflicting opinions held regarding its identity and its rôle in cystitis and the confusion of nomenclature until recently prevailing.

A Case of Pseudo-Hypertrophic Muscular Paralysis.—George Rose reports a case in a boy aged nine years, in which the salient features were great muscular weakness, enlargement of certain muscles and wasting of others, loss of knee jerk, and diminution of other reflexes, and hyperæsthesia to pain. The microscopic appearance of pieces of the biceps and gastrocnemius is given, and the article is illustrated by photographs of the patient in various positions.

Clinical Lecture on Pulmonary Phthisis and its Treatment.—By Alexander James. A continued article.

Zeit. f. Tuberkulose u. Heilstättenwesen, vol. i., No. 6.

On the Treatment of Tuberculosis by Sodium Cinnamate.—A. Mann describes his results with intravenous injection of betol or the sodium salt of cinnamic acid, the active constituent of balsam Peru, with some reports of cases that seem so encouraging as to fully justify the favorable conclusions drawn. The method employed is essentially that of Landerer, and consists in the use of gr. $\frac{1}{100}$ to $\frac{1}{50}$ as a beginning dose, which is gradually increased to gr. $\frac{1}{4}$ or $\frac{1}{3}$. The injections are repeated every other day, and made into the median basilic or cephalic vein. The object is to produce at the site of local injury an acute inflammatory reaction which shall produce a healthy cicatrization of the tuberculous area. No untoward effects have been noted except slight drowsiness following the use of unnecessarily large doses.

Aneurism of the Abdominal Aorta in Connection with a Tuberculous Perityphlitic Abscess.—Henssen reports a case of moderately acute pulmonary disease in which indefinite pains in the appendicular region were accompanied by a slowly increasing doughy tumor in the same locality. This increased for nearly a month, in spite of palliative treatment, when a second tumor developed, which gave all the typical physical signs of an aneurism of the abdominal aorta. Four days later, after several copious movements of the bowels, the cæcal tumor disappeared and there was left in its place only a rounded cord-like structure. The supposition is that the appendicular abscess ruptured into the intestine, while the aneurism was due to pressure on the aorta either from inflammatory infiltration of the tissues or from enlarged mesenteric lymph glands.

The Rest Cure in Phthisis.—S. Bernheim believes that rest, absolute and complete, is the most important element in the treatment of the tuberculous patient. Even the pulmonary gymnastics advocated by many authorities he considers ill-advised and apt to cause progression of the disease, while a state of entire bodily and mental inactivity gives the natural forces the best opportunity to make a stand against the advance of the morbid process. The risks of auto-intoxication are diminished, organic waste is lessened, the functions of the lung and heart are regulated, the febrile movement is controlled, and every possible aid is given to those most important adjuncts in the treatment, viz., food and fresh air.

The "N" and "O" Therapy in Pulmonary Tuberculosis in Reference to the Resort Lippspringe.—B. Rohden describes the peculiar conditions prevailing at this resort where, owing to gaseous emanations from the ground, the amount of nitrogen present in the air is considerably higher than the normal percentage. As a result of the ensuing diminished quantity of oxygen available for respiration a reduction of metabolic activity and oxidation processes takes place, which is of great benefit in many forms of phthisis. It is particularly the so-called arterial types of the disease in which there is increased tissue consumption that are favorably affected, while in asthenic cases treatment in this atmosphere is contraindicated.

Some Observations on the Treatment of Pulmonary Tuberculosis.—H. Naumann ascribes great value to plentiful feeding, and believes that in a large number of cases the predisposition to the disease rests on a condition of chronic malnutrition. In some individuals, however, no amount of increase in the food consumption produces any effect, and rest cures are equally unsatisfactory, while graded exercise by stimulating tissue change produces a gradual alteration in constitution which leads to marked improvement. Patients should be sent to climates as different as possible from those in which they were taken with the disease, while still more important is the stimulating effect of frequent changes of climate.

A Contribution to the Knowledge of the Cultivation and Staining of the Tubercle Bacillus.—A. Marmorek says that the first organisms to develop after a culture medium has been inoculated with tubercle bacilli are deficient in the thick fatty or waxy protecting sheath which surrounds more mature individuals. The result is that the entrance of aqueous staining solutions into the interior of the cell is not impeded and the organism stains very readily, while on the other hand the decolorizing action of alcohol and acid solutions is not so strongly resisted as usual and the color is easily discharged.

The Significance of Pulmonary Tuberculosis for Life Insurance Companies.—P. Croner, as the result of a very exhaustive study of the statistics of the subject, considers that sex, occupation, age, family history, previous association with tuberculous patients, previous pulmonary diseases, conformation of the thorax, etc., are all of greatest importance in estimating the liability to the development of tuberculosis, and that all persons in whom there is reason to suspect the slightest tendency to predisposition should be rated as distinctly poor risks.

A Protective Mask for Polyclinical Use.—S. Cohn describes an easily manufactured paper mask intended to be applied to each dispensary patient on entering the examining-room, thereby preventing the risk of infection through exhaled particles of mucus or expectoration. When the room is left the mask is removed and thrown away.

Institutional Treatment of Phthisis.—By J. Gabrilowitch.

Tuberculosis, Congestion, and Blood.—By H. W. Blöte.

La Pratica del Medico, December, 1900.

Rectal Feeding in Typhoid Fever.—Giovanni Stefanile cautions against too quick resorting to rectal feeding, a milk diet being well tolerated by many patients. Should it, however, cause uncoercible nausea and vomiting, rectal feeding should certainly be tried. The author prefers Boas' formula, which, leaving out the starch, is as follows: Coffee, 250 gm.; well-beaten yolk of two eggs; chloride of sodium, 2.6 gm.; red wine, 15 gm. Patients, as a rule, are inclined to rebel against this method of feeding, and must be soothed and reassured by careful explanations of the value of allowing the stomach to rest.

Morbid Blushing.—Gaspare Basile describes several cases. He believes that this disorder should be regarded as a manifestation of neurasthenia and hysteria. He mentions the two affections together, considering neurasthenia to be hysteria as developed in man, and hysteria as neurasthenia developed in woman. He considers hypnotic suggestion the best treatment.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LATE QUEEN, PROFESSIONAL REGRETS—SOCIETIES—PLAGUE—JACOB MEMORIAL—THORNE MEMORIAL—INDISPOSITION OF DUKE OF YORK—PUBLIC HEALTH—A NOTABLE WILL—DEATH OF MR. VERNON.

LONDON, February 1, 1901.

THE death of the Queen and its consequences; the demise of the crown; the accession of Edward VII.; the preparations for the great funeral to take place to-morrow; the numerous, and often unanticipated, changes necessitated by the commencement of a new reign: these and allied subjects have almost excluded medical matters from attention all the week. Even in our societies, colleges, and other institutions more or less connected with the profession, the first business has often been to pass resolutions of condolence with the royal family and of loyalty to the new sovereign; or if not formal resolutions, expressions of those sentiments in other forms.

I told you in my last that the Medico-Chirurgical Society, meeting on the day of the late Queen's death, after a

few words by the president on the sense of loss felt by the whole nation, at once adjourned. The society will meet on Tuesday next, when a loyal address to the King will be moved by Lord Lister and seconded by Sir W. S. Church, P.R.C.P. At the Medical Society on Monday last the president, Mr. J. Morgan, opened the meeting by referring to the irreparable loss of the nation, and proposed that the humble expression of their grief and their extreme admiration of her late Majesty should be forwarded through the proper channels, together with the tender of their deep sympathy and loyalty toward his Majesty King Edward VII. Other societies, as I have said, followed in similar terms. In fact the stream of expressions of regret, condolence, admiration, and loyalty is swelling day by day, and will doubtless continue even after to-morrow's sad pageant and day of mourning. Those already received from strictly professional bodies are too numerous to quote, so with one more sample I must pass on to other topics.

The Clinical Society met on January 25th, when Mr. Gould took the chair. He said he had been asked to do so by the president, Sir Douglas Powell, who felt unable to take his place after the important part he had played in the late sad event of which all were cognizant. As the society is a scientific one, the Council did not think it necessary to postpone the proceedings, which consisted at this meeting in the exhibition of cases for which all arrangements had been made. Nevertheless Mr. Gould said they could not meet without giving expression to the sense of personal loss which they shared with the whole empire in the death of the greatest monarch of modern times. During her reign of more than sixty years great advances had been made in scientific medicine. The late Queen gave her implicit confidence to her medical advisers; she was the first British monarch to submit to vaccination, and the first to be submitted to anæsthesia at a time when prejudice withheld this boon from women in their hour of nature's need; on antiseptic surgery she set her seal by granting to Lister the highest dignity ever conferred on a medical man as such; in sanitary science her interest was shown, when cholera threatened, by her keen interest in the precautions taken under the superintendence of the late Sir R. Thorne. Mr. Gould closed with an expression of the great loss sustained by the death of the late Queen, and an assurance that all would join with him in looking forward with a devout prayer of "God save the King." A number of interesting cases were then exhibited, among which I may name: generalized sclerodema with Raynaud's disease; myasthenia gravis; aortic regurgitation, apparently due to rupture of a healthy valve, in a man aged twenty-one years; a case of dextrocardia, probably congenital, in a woman aged forty-six years; unusually great cardiac dilatation in a man aged twenty-two years; multiple fibro-neuromata or Recklinghausen's disease.

Nurses are by no means always such as novelists speak of them. Householders who have had to employ them are apt to describe them as nuisances, and some of them have never learned to keep their proper place. Lately a district nurse refused to attend the patients of one of the doctors in the district, and her local committee upheld her conduct. When the association decided that it was the nurse's duty to obey the medical man without commenting on his mode of treatment, the committee resigned. It is time that all nurses were subjected to a more sensible discipline.

The matrons and superintendents are indeed exacting enough. In fact, just now there is an outcry against their severity and alleged cruelty. Certainly a woman can oppress her own sex in a way that a man cannot, and there is no doubt that matrons insist on obedience to themselves more than to the doctors—their own superior officers. Some, indeed, seem not to recognize that they have superiors, hence those trained under them assume airs which are intolerable. Last year Mr. Gant brought out a little book on "Mock Nurses," in which he exposed the conduct of some of the black sheep and reaped for his pains a good deal of odium. He is, however, a warm friend of the good nurse, and said nothing to shame any one who followed the calling uprightly. But even he did not touch upon the matron, with whom much responsibility rests and of whom committees often seem afraid. Hence there is too much despotism in nurse training, and it is often said that women are particularly unfit to be entrusted with absolute power. Perhaps the present outcry against tyranny may lead to committees asserting their authority.

No fresh cases of plague have occurred at Hull, and the steamer *Friary* has been released. An infected steamer put in at Bristol, but none of the crew exhibited any symptoms and the vessel was disinfected and released. The sanitary officers at Hull deserve credit for the prompt manner in which they successfully met the emergency.

A "Jacob Memorial Fund" has been started. The committee includes the presidents of both the Irish colleges and all the leading physicians and surgeons in Dublin. Dr. Jacob, whose death I have previously mentioned, left but a slender provision for his widow and daughters, and the fund will be for them. Jacob was an earnest reformer, and medical reform does not pay. It hindered him in practice, absorbing too much attention. The Irish profession owes him an enormous debt of gratitude for his efforts and achievements. If he had stuck closely to his practice and avoided public work he would have made a large fortune, for as an ophthalmologist few could equal him.

A memorial tablet to Sir Richard Thorne Thorne has been placed, by the members of the medical department of the local government board, in St. John's Church, Woking, where he of late years attended.

The indisposition of the Duke of York, in the excited condition of the public mind, caused some anxiety at first; but it speedily subsided on the assurance that it was a mild attack of German measles, and that this disease was not dangerous, merely requiring simple regimen and rest in bed or indoors.

The mortality returns continue favorable. The death rate in London for the last four weeks has been 17.9, 19.6, 18.7, and 17.6 successively. Croydon and Derby have had the lowest rates for the first month of the year—the former's average being 12.8, the latter's 13.5.

Quite a number of hospitals and other charities benefit under the will of Mr. Samuel Lewis, a money lender, who amassed a large fortune and died recently.

The death of Mr. Bowater Vernon, ophthalmic surgeon to St. Bartholomew's Hospital, is announced. He had been in ill health for a long time, and died on the 28th ult.

A FAMILY HISTORY OF ANÆMIA.

To the Editor of the Medical Record.

Sir: After reading Dr. Dana's article on pernicious anæmia in its relations to heredity, in your issue of December 1st of last year, I was led to look over my brief notes of a case which I saw some years ago with a friend whose name I withhold, as he thinks it desirable to avoid the chance of identification.

The patient was a woman in late middle life. Her sister thought she had been losing color for three or four years. She had been under the care of my friend for about a year with gradually increasing anæmia. She had been taking a fair amount of food, mostly milk, seldom vomiting, but the quantity had been growing gradually less until, at the time of my visit, it was about one and a half quarts per diem.

I think I was asked to see her more with a view to some change in, or addition to, the diet than because any doubt was felt about the diagnosis.

There was looseness of the bowels without much pain. Menstruation was regular until about eight weeks before, with no trouble. She herself attributed the severity of her sickness to a shock. She was extremely white, not yellow, and emaciated. There was no œdema and the urine was normal (not examined quantitatively). The pupils were wide, there was a blowing first sound of the heart, and nothing was to be found by careful palpation of the abdomen. No blood examination was made, for reasons given below. The white color and the emaciation differentiated this case from the typical "idiopathic anæmia," but the gradual appearance and long duration of the symptoms, together with the small amount of nourishment taken, might have accounted for this, so that in the entire absence of decisive symptoms pointing in any other direction we fixed upon this condition as our diagnosis. She died a few days later. My notes speak of similar cases in a brother and sister, and also in the father with an interrogation mark. Upon writing to my colleague for further information, I received the following reply:

Cambridge, February 5, 1901.

"Dear Dr. Edes: The reason we did not have the blood examined was because the patient and her sister did not wish to have it done. Besides, the diagnosis was perfectly evident, and I could not urge the examination of the blood on the ground that it would help clear up the cause of her sickness.

"In answer to your second question; a brother died about six years before she did, in the same way, from the same cause, and at about the same age.

"An older sister had a sickness before our patient was ill with what seemed to be the same trouble, but in two years she got better. About two years ago the same sister had another attack, which lasted somewhat more than a year, from which she has recovered fairly well.

"I think the father died of heart disease.

"You ask how authentic is the history of her father's and brother's cases. I never saw her father, but I saw her

brother twice in consultation with Dr. ——. It was long before examinations of the blood were made to assist in the diagnosis, but it was as clear a case of pernicious anæmia as I ever saw, and the post-mortem examination confirmed it. There were no lesions of the body except excessive anæmia."

ROBERT T. EDES, M.D.

BOSTON, MASS., February 12, 1901.

THE NEW MEDICAL BILL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: We have had a bill introduced in the legislature of this State which is of vital importance to the medical profession, medical colleges and medical institutions, and to the public generally. This bill, if enacted into law, will compel every person who treats disease, regardless of the method he employs, to comply with the medical laws.

The necessity for the enactment of this bill seems very plain. Under an old decision of the supreme court of this State, in the case of Smith vs. Lane, it was held that unless one gave medicine he did not practise medicine.

The result of this decision has been that people who desired to evade the law have adopted some cunningly devised name, as "osteopath," "hydropath," etc., and, refusing to give medicine, have set themselves up as being competent to treat disease, and the authorities are not able successfully to prosecute them.

The existing medical laws, as they are at present enforced, are incentives to ignorant and unscrupulous people to adopt some peculiar name or title, and so avoid the necessity of that careful preparation the law says a person should have before being allowed to practise medicine. The law places obstacles in the path only of those who desire to perfect themselves so as to be able to practise intelligently.

About three years ago the osteopaths had a bill introduced in the legislature which sought to legalize their practice, but the measure failed. They have this year attempted the same thing, and their bill, which has been introduced, is stronger and has greater backing than before. It will seek to give the people who have not perfected themselves as physicians are perfected, the right to treat any and all disease by the method known as "osteopathy." If they gain this privilege, it cannot be expected that other practitioners will be content to comply with the requirements of medical colleges when they can obtain the same standing in the community by studying at some osteopathic college. This latter course may not give them the same standing professionally, but it will enable them to rank as well with the community as the person who has received a thorough medical education.

Another bill has been introduced compelling the regents to endorse the diploma of any physician who has passed the State Board of Medical Examiners of any other State. If this applied only to States where the requirements are similar, although inferior to our own, it would be bad enough; but it goes further and applies to all States. Should this bill become a law, students can then go to some State where the requirements are almost nothing, and having received the right to practise there, come to New York and be allowed to practise here. This will be an unfair discrimination against the medical colleges of this State, will make a farce of our medical laws, and will certainly not be of advantage to the community.

It seems to the writer that these are matters which should interest every person, physician or otherwise, who believes in upholding the present high standard of medical requirements in the State of New York, and who has the interest of the community at heart. We trust that they may interest you, and that you will use every honorable means at your command, first, to assist in the enactment of the bill known as the Bell bill, compelling every person who treats disease, whether with or without drugs and medicines, to comply with the medical laws; second, to assist in the defeat of the Seymour bill, which would give a legal standing to a class of incompetent practitioners known as "osteopaths"; and third, to assist in the defeat of the Adler bill, which seeks to let down the bars so that medical men of possibly inferior education and ability may be allowed to run the State of New York.

The writer is engaged in what he hopes will be considered a commendable effort to retain for the medical profession of the State of New York the proud position it holds in the eyes of the world to-day, and to insist that the legislature will continue to protect the community from incompetent medical practitioners by compelling compliance with the medical laws as a prerequisite to practice.

FRANK VAN FLEET, M.D.

Chairman of the Committee on Legislation of the Medical Society of the State of New York.

Surgical Suggestions.

Vesical Hyperæmia, of mild degree, is best treated by irrigation with a one-per-cent. solution of boric acid, followed by a one-fourth-per-cent. solution of nitrate of silver.—BIERHOFF.

Objects of Drainage in Abdominal Surgery.—The chief purposes for which drainage is employed are as follows: 1. To drain away existing septic material. 2. To afford an exit for the sepsis when the operator fears he has possibly infected his patient. 3. To provoke adhesions and thereby wall off weak spots from the remainder of the abdominal contents. 4. To keep the peritoneal cavity free of blood and other fluids. 5. To allow of a more certain knowledge of the conditions present in the abdomen. (6) Gauze drains are sometimes employed as tampons to control hemorrhage.—DR. J. W. LONG, *Annals of Gynæcology and Pediatry*, December, 1900.

Hints.—SURGICAL NEEDLES. It is a good thing to remember that surgical needles require sharpening about as often as scalpels, and that the use of a hone and a little emery powder will restore to usefulness many needles in an apparently hopeless condition.—DRAINAGE TUBE. It is well to remember that a drainage tube is a foreign body, and hence an evil. Clean surgery and proper attention to hæmostasis reduce considerably the number of cases in which drainage is indicated, and it seems to be the tendency of the best surgeons to do the least draining.—A POULTICE is an excellent thing in its place, but there is no earthly reason for ever making it out of dirty vegetable matter. Gauze and absorbent cotton soaked in weak, warm antiseptic solutions, and covered with protective, are the only poultices allowable in modern clean surgery. —IN CASES OF SEVERE HEMORRHAGE FROM THE LUNGS, due to external wounds, the chest should be immediately opened, and a good-sized drainage tube inserted. This causes pneumo-thorax, and the pressure of air upon the lungs will greatly help in controlling the bleeding. The intravenous injection of saline solution must also be immediately employed.—IN CRUSHING ACCIDENTS in which the limbs have been caught in machinery it is very difficult to cleanse the wound properly, owing to the fact that the parts are much covered with grease due to lubricating substances. Ordinary gasolene is an excellent thing wherewith to remove this grease; it causes no pain, dissolves away the grease, and leaves a clean surface upon which watery solutions of antiseptics can exert their full power.—CHILDREN who are prepared for operation must not be kept as long without food, prior to anæsthesia, as is proper in adults. Children weaken rapidly from hunger, and it is best to give them easily digested food up to three or four hours before the operation. As in the majority of instances they need not know that an operation is contemplated, there is none of the inhibitory effect upon digestion, caused by fear, that is so often observed in adults.—IT IS IMPORTANT to remember that children, especially in crowded, poor districts, sometimes have empyema without even complaining of chills or showing a rise of temperature, and that the disease is often so insidious as to lead simply to general ill-health long before the parents become alarmed at the child's condition. Any child that has become gradually run down in health should be stripped and carefully examined for empyema, when no other cause is evident. —*International Journal of Surgery*, December, 1900.

Extemporized Dressings.—Cheesecloth cut into strips or squares is rendered alkaline by boiling for twenty minutes in a solution of washing soda (two

ounces to a quart), then wrung out and boiled again in clear water, previously boiled and allowed to settle. It is then passed through a bichloride solution (1 : 200). Just before using it is wrung out in bichloride solution (1 : 2,000).—*The Clinical Review.*

Rodent Ulcer.—Rub in resorcin powder each night, after removing crusts.—BLOMFIELD.

Infantile Eczema (dry, vesicular, and papular).—

℞ Zinci oxidi,
Amyli,
Adipis lanæ.....āā 5.
Petrolati..... 10.
Hydrarg. oxid. flav..... 0.25–0.50
M. ft. pasta.

—LEISTIKOW.

Gelatin in Aneurism.—Gelatin injections should be kept sterile. When large quantities are injected, great pain may be produced. Aneurismal pain is usually lessened; the tumor becomes firmer by large organized clots forming.—NIETERT.

Rectal Operations require such profound anæsthesia that they are very favorable for the spinal anæsthesia method, the moment there is the least fear of general anæsthesia. Opiates may be given early enough by the mouth to obtain an effect before the cocaine analgesia has ceased, so that the patient is saved not only operative but post-operative pain.—CHASSAIGNAC.

Treatment of Burns of Second Degree.—Probably the best local application for burns of the second degree is the solution of picric acid. This is non-toxic in the strength in which it is usually employed and is antiseptic and analgesic. It also possesses the advantage of coagulating the albumin, and thereby diminishes the serous discharge and hastens the reparative process. It has been employed for several years in the Charity Hospital of Paris. It may be used in aqueous or hydro-alcoholic solution. It is soluble in water in about five per cent. It is readily soluble in alcohol. The addition of five to eight per cent. of alcohol not only makes a stronger solution of the acid possible, but seems to impart its own properties, which renders it more effective. The picric-acid solution also seems to produce a smoother and better cicatrix.—S. R. MILLER.

Surgical Intervention in Gastric Ulcer.—A. Heydenreich (*Wiener med. Blätter*, 43, 1900) says that the first indication for surgical intervention in gastric ulcer is the perforation of the stomach wall. This perforation is almost always followed by a fatal peritonitis; in this case intervention is absolutely necessary and must be accomplished at once. The laceration must be sutured and the peritoneum carefully looked after. Excision of the ulcer does not appear necessary. If the situation of the perforation opening or the infiltration of the surrounding tissue renders the technique of suturing difficult or impossible, an attempt might be made to close the opening with omentum, or iodoform-gauze drainage may be used. A second indication is the contraction and narrowing of the pylorus. Food stuffs are not passed from the stomach into the duodenum, the patient becomes poorly nourished, and is in danger of death by inanition. Still another indication lies in the cicatricial adhesions of the ulcer region with the surrounding organs or the abdominal walls; purulent accumulation in the neighborhood of the ulcer is another indication. In the determination of hæmatemesis as an indication for surgical operation, a distinction must be drawn between the severe hemorrhages and the smaller, oft recurring ones. In the very severe hemorrhages surgical intervention is not recommended. In instances of milder hemorrhages, however, which recur weekly and monthly, and which lead to marked anæmia and perhaps to death, surgical intervention may be efficacious provided it be undertaken early enough. Excision of the ulcer is no longer practised, but pyloroplasty and gastro-enterostomy. In conclusion, surgical interventon is indicated not only in complicated cases, but also in those in which without previous complications a methodical, rational, and long-continued treatment has been useless.

Society Reports.

THIRD PAN-AMERICAN MEDICAL CONGRESS.

Held in Havana, Cuba, February 4, 5, 6, and 7, 1901.

SECTION ON MEDICINE.

(*Continued from page 270.*)

An Epidemic of Yellow Fever.—DR. PEDRO ALBARRÁN, of Havana, described an epidemic of yellow fever occurring in San Diego del Valle twenty years ago. Out of a population of three hundred, sixty-one were attacked and forty-eight died. The interesting point about this epidemic was that the native Cubans, both blacks and whites, suffered the most. The disease was traced to a Spanish soldier who died in the outskirts of the town three days after his arrival. The Cuban who nursed and buried him developed the disease five days later. The epidemic lasted all summer, and was stopped by the advent of cool weather. Two cases occurred the following spring, but none developed from these.

Prophylaxis of Yellow Fever.—DR. JOSÉ A. TRÉMOLS, of Havana, presented a communication in which he stated that there was an antagonism between phosphorus and yellow fever. He had observed that unacclimated foreigners working in factories where phosphorus was used, never suffered from yellow fever. After a brief study of phosphorus and its compounds formed upon contact with the air, he presented a comparison of the lesions of yellow fever and those observed in cases of phosphorus poisoning. He urged further study of this subject, as it seemed to him it might lead to discoveries of great moment in the way of the prevention and treatment of yellow fever.

Need of a Department of Public Health in the United States Government.—DR. LISTON H. MONTGOMERY, of Chicago, read a paper in which he urged the creation of a new secretaryship of public health in the United States government, the secretary to have a seat in the President's cabinet, and to hold equal rank with the other secretaries.

The Necessity for a More Careful Investigation as to the Cause of Outbreaks of Infectious Diseases.—DR. ALVAH H. DOTY, health officer of the port of New York, sent a communication which was read by Dr. Ramón Guiteras, of New York (see page 281).

DR. MORENO said that he was convinced yellow fever was often spread by relapsing cases, these relapses often occurring as late as the fifteenth day. He thought the doctrine that clothing would not carry the germs of disease was a dangerous one, for clothing certainly could convey diphtheria and scarlet fever.

DR. PIQUERO, of Havana, thought Dr. Doty's paper was a most important one, and hoped it would be translated into Spanish for the benefit of those members of the congress who were not familiar with English.

DR. JOHN GUITERAS said that this paper contained the first clear expression of modern quarantine views

which had come under his notice. Since 1881 the speaker had always maintained that the first case of yellow fever reported was never the first case in the epidemic, and he had frequently not only demonstrated the previous existence of mild cases, but had even found evidence of fatal cases occurring before the first recorded case. The occurrence of mild cases was of very great importance in connection with yellow fever. Such cases in the negro were often unrecognized, and in native-born children also mild cases by which the disease was spread frequently occurred. Scarlet fever was similarly spread by unrecognized cases in negroes, and the speaker cited an epidemic of this disease in Savannah which had originated in this way.

Dr. Hodgson mentioned a case, told him by Dr. Carter, of a vessel sixty-two days out from Rio, on which a case of yellow fever appeared three days after arrival in New York.

Major Gorgas, chief sanitary officer in Havana, said that this question of mild cases of yellow fever was a very practical one in Havana. The large majority of yellow-fever cases were now recognized and reported, yet some of the mild ones were overlooked, and the problem was what to do in regard to these mild cases.

Dr. John Guiteras said that physicians practising in Havana and other tropical regions must be educated up to the point of admitting the existence of these mild cases in negroes and native children. The mild cases would then be reported, and so in winter the chain that kept up the endemicity of the disease would be broken. The case of yellow fever occurring on board a vessel sixty-two days out from Rio, just mentioned by Dr. Hodgson, was readily explicable on the mosquito theory.

Dr. Porter, of Key West, cited an instance in which, out of a crew of fourteen, eleven died of yellow fever before reaching Rio. The captain, on being questioned subsequently, said that there were no mosquitos on board the ship. The question raised by Dr. Doty regarding the non-transmission of infectious disease by clothing was not new. The speaker had long believed that sunlight and air were nature's disinfectants, and very powerful ones.

Dr. Marcour, of the United States Marine-Hospital service, cited the case of the U.S.S. *Plymouth* on which yellow fever broke out each time she returned to the tropics before she had touched at an infected port.

Dr. Dámaso T. Lainé, of Havana, surgeon U. S. A., referring to the case cited by Dr. Porter, said that not much stress should be laid on the captain's statement regarding the freedom of the vessel from mosquitos. Not long since, he said, he boarded the *Mexico* in Havana harbor in company with Dr. Guiteras to look for mosquitos. They were told by the officers and passengers that there were no mosquitos on the ship, yet on going into several of the cabins they found great numbers, even in the rooms of passengers who said they had not seen one.

Dr. Porter said he did not wish to be understood as rejecting the mosquito theory of the transmission of yellow fever. He only counselled caution and a repetition of the experiments by an international commission of bacteriologists.

Dr. Holbeck, of Charleston, S. C., said it was evident the entire history of yellow fever must be rewritten, and he urged each one present to use his influence with his own government to further the appointment of a Pan-American yellow-fever commission.

Madura Foot.—Dr. C. M. Desvernine and A. Diaz Albertini, of Havana, reported two cases of madura foot occurring in Cuba. One of the patients and the amputated foot of the other were shown to the section. The parasite (Streptothrix maduræ) was described and preparations of the same were exhibited.

Dr. Thomas N. Calnek, of San José, Costa Rica, said that he had seen many cases of this disease in Costa Rica, where it was generally confounded with elephantiasis. He believed the disease was curable in the early stages when the nodules were small. Elephantiasis was rare, but madura foot quite common in that country.

Dr. Debayle, of León, Nicaragua, had seen many cases, the disease being not at all rare in that country.

Dr. Moreno, of Havana, did not think that the absence of filaria in suspicious cases should be held to negative the diagnosis of elephantiasis.

Affections Noted in Smokers.—Dr. Ramón García Mon, of Havana, read a paper on this subject. In Cuba, where smoking was carried to such an excess, he said, one had many opportunities for studying the symptoms of tobacco poisoning. He first described the effects of tobacco smoke on the mucous membranes of the mouth, pharynx, and larynx, and spoke of the nicotine and other products of combustion of tobacco. He compared alcoholic inebriety with tobacco poisoning, and explained that the latter depended not only upon the quantity and quality of the tobacco smoke, but also upon the peculiar susceptibility of the smoker. Tobacco intoxication might be either acute or chronic, and its effects might be divided into two great groups according as the nervous or the circulatory system was chiefly influenced. The main symptoms on the part of the nervous system were vertigo, tremor, insomnia, amnesia, and amblyopia. Those on the part of the circulatory system were cardiac palpitation and tachycardia and arteriosclerosis.

Borras Fever.—Dr. Francisco Müller, of Havana, presented a communication in which he held that there was no distinct pathological entity called "borras fever," as held by many Cuban physicians, but that what was called by this name might be either yellow fever or malaria or typhoid fever. He described these three types, and showed that they could not be classed as one disease, but that their symptoms corresponded to those of the three fevers mentioned.

Dr. J. R. Avellanal, of Bejucal, Cuba, said that he fully accepted in the solution of the problem of borras fever the action of the three great pyrexias, malaria, yellow fever, and typhoid fever. He did not consider of much importance the arguments brought forward in support of the theory that borras fever was a disease *sui generis*, and indeed a careful study of the symptoms of the various types led to the conviction that this theory was incorrect. The absence of the malarial parasite in certain cases did not prove that it might not be present in others, and it was not always possible to obtain Widal's reaction in the typhoid form, since this was an aborted typhoid which ran its course in less time than was needed to obtain this reaction. Whatever doubts there might be as regarded diagnosis, the treatment of borras fever, so called, was simple enough, consisting in the administration of quinine together with antiseptics and evacuants.

Malta Fever in Havana.—Dr. Emilio Martinez, of Havana, described two cases under his care, one of a fever with five distinct attacks resembling closely Malta fever of the undulating type, the other of a continued fever of long duration. The diagnosis in these cases was difficult, as they fortunately seldom came to autopsy, and the author urged the importance of obtaining blood reaction with cultures of the micrococcus melitensis. He was quite confident that many cases of so-called urban fever, infectious fever, enterosepsis, etc., occurring in Havana were really cases of Malta fever.

Malaria.—Dr. Ernesto Edelmann, of Havana,

presented a communication in which he advocated a return to the older theories of malaria, maintaining that the germ lived and multiplied in marshes and infected all living things—many birds, reptiles, and quadrupeds—that might be exposed to its influence. The germ was the same whatever species of living thing it might infest. If the mosquito could spread the disease, so could all external parasites deriving nutriment from human blood.

Appendicitis.—Drs. Gustavo Duplessis, Gregorio Perez Piquero, and Joaquin L. Jacobson, of Havana, presented a communication containing observations derived from their experience with appendicitis. The disease had seemingly been more frequent in Havana during the past year than previously, which they attributed in great part to the influence of influenza. In the paper were discussed the symptomatology, diagnosis, prognosis, and pathological anatomy of the disease, together with the indications for operative treatment.

Rabies in Havana.—Dr. E. Acosta, of Havana, presented a report of the cases of rabies treated by the Pasteur method at the bacteriological laboratory of the *Crónica Médico-Quirúrgica* of Havana, during the past fourteen years. The statistics of recoveries differed but little from the general average.

Treatment of Yellow Fever.—Dr. José Vila, of Havana, detailed his plan of treatment of yellow fever, consisting in the use of evacuants combined with intestinal irrigation. The earlier these measures were instituted the more favorable were the results. The diet and other accessories of treatment must vary according to the special indications in each case, but the capital indication was for the rapid elimination of the specific poison.

Dr. Francisco Portela, of Havana, reported a very severe epidemic of yellow fever occurring in Guanajay, Cuba, in 1889. He had tried various modes of treatment without success. Sternberg's method had been tried with no definite results, but on combining the internal administration of corrosive sublimate and an alkali (Sternberg's method) with Vila's evacuant treatment his success had been very marked. He had used this combination during the past twelve years with great satisfaction.

Intestinal Complications of Malaria.—Dr. Rudesindo García Rijo, of Sancti Spiritus, Cuba, presented a communication on this subject. Intestinal complications were frequently observed, he said, in the subjects of malaria, but they were not always directly traceable to the action of Laveran's hæmatozoon. They might be the result of manifold influences, not all of them of an infectious nature, and were often due to individual idiosyncrasy. It was very important in these cases to search carefully for the underlying predisposing causes, as upon their discovery and correction depended in very great part the success of our therapeutic measures.

The following papers were also presented by their authors or read by title: "Clinical Notes on Malarial Hæmoglobinuria as Observed on the Atlantic Coast," by Dr. Leonard John Stegall, of Costa Rica; "Contribution to the Study of the Influence which the Ascarides Exercise in the Organism, Especially in the Pyrexias," by Dr. Luis H. Debayle, of León, Nicaragua; "Historical Review of Medicine in the Nineteenth Century," by Dr. Eduardo F. Pla, of Havana; "Yellow Fever," by Dr. J. W. V. R. Plummer, of Key West, Fla.; "Impure Drinking-Water the Paramount Cause of Malarial Fevers," by Dr. John W. Ross, of Clarkesville, Tenn.; "Diagnosis of Yellow Fever in the Native," by Dr. J. L. Dueñas, of Havana; "Senile Athrepsia," by Dr. Ernesto Edelmann, of Havana; "Yellow Fever," by Dr. Adrian Hava, of New Orleans, La.; "Contribution to the Study of Yellow Fever," by Dr. Ernesto Edelmann, of Havana; "Detection of Sugar in the Urine," by Dr. Francisco G. de Vildósola, of Havana; "Yellow Fever," by Dr. Ramón Garganta, of Havana; "Tetanus," by Dr. Florencio Villuendas, of Guantánamo, Cuba; "Bilious Remittent Malarial Fever," by Dr. Florencio Villuendas, of Guantánamo, Cuba; "Demonstration of the Electro-Arc-Chromolume," by Dr. J. Mount Bleyer, of New York; "Diagnosis of Yellow Fever," by Dr. L. Dueñas, of Havana; "Tuberculosis in Man and Beast," by Dr. John A. Kelly, of Brooklyn, N. Y.; "Etiology," by Dr. Elmer Lee, of New York; "Physical Diagnosis," by Dr. W. H. Vandenburg, of New York; "Remarks on Tuberculosis," by Dr. Liston H. Montgomery, of Chicago, Ill.; "The Animal Body as a Secreting Gland, and the Relation of the Pathology of this Type of Structure to Disease," by Dr. J. S. Foote, of Omaha, Neb.; "On the Responsibility of Drug Takers, Particularly in Alcohol and Opium Inebriates," by Dr. T. D. Crothers, of Hartford, Conn.; "The Clinical Significance of Indicanuria," by Dr. Judson Daland, of Philadelphia.

SECTION ON HYGIENE AND QUARANTINE.

Because of the comparatively small number of papers presented in each section, and also because of the similarity and overlapping of the subjects, it was deemed best to consolidate the several sections of bacteriology, general hygiene and demography, marine hygiene and quarantine, and veterinary surgery.

A Bacteriological Commission for the Study of Quarantinable Diseases.—Dr. Henry B. Holbeck, of Charleston, presented a paper in which he urged the necessity of the organization of bacteriological commissions for the study and investigation of quarantinable diseases, under the formation and control of the governing authorities of the countries interested. The means of betterment of maritime hygiene and quarantine, he said, presented one of the greatest problems confronting civilization, the solution of which was essential to the removal of dangers confronting commerce and humanity. Already science had done much in this direction in the determination of the pathogenesis, mode of transmission, and incubation of various diseases. We knew now how malaria was transmitted and had learned that in its prevention we must turn our arms against Anopheles. There remained the problem of yellow fever which would be solved by scientific study and investigation, but never by the promulgation of theories. Tons of paper and gallons of ink had been wasted in writing of yellow fever, but without advancing one step nearer the true solution of the mystery. Concerted action by a scientific commission working under authority of the various governments was what would remove the uncertainty now existing regarding the majority of quarantinable diseases.

The paper was discussed by Drs. Wilson, of Havana; Glennan, of the United States Marine-Hospital service, and Porter, of Key West, all the speakers being in favor of Dr. Holbeck's proposition.

Micro-organisms in the Air of Havana.—Drs. Nicolás Carvallo and Julio Cisneros, of Havana, presented a paper on this subject. They had made cultures from plates exposed to the air in various parts of Havana, finding microbes of the greatest variety—staphylococci, bacilli of diphtheria, Sanarelli's bacilli, micrococci, saccharomycetes, aspergilli, etc. They also found in one locality conidia resembling Bra's alleged parasite of cancer.

The Sanitation of Havana.—Dr. Erastus Wilson, of Havana, read a paper detailing the defects in the municipal sanitation of the Cuban capital and suggesting measures for its betterment. He compared

the city of Havana to an individual who consumed too much food and drink while the functions of the excretory organs were deficient. The water supply of the city was most plentiful, but the drainage being inefficient the water, carrying with it organic impurities, was absorbed into the soil and was thus an important factor in the unsanitary condition of the city. There were radical defects also in the building-laws. The speaker urged the reorganization of the board of health with sufficient discretionary powers to deal summarily with common nuisances, and believed much good would result from the establishment of a corps of women sanitary inspectors to make domiciliary visits.

The Work of the Marine-Hospital Service in Havana.—Dr. Glennan read a paper describing the work of the United States Marine-Hospital service in Havana, which consisted not only in the defence of Cuba against various infections which might be introduced in vessels from abroad, but also in the protection of the United States against yellow fever introduced from the port of Havana. This second object was effected by the disinfection of all ships, baggage, and mail, and also in the granting of health certificates to yellow-fever immunes.

Dr. Torralbas spoke of the great benefit that Cuba had derived from the service of the Marine-Hospital officials and the carrying out of the methods introduced by them. Under the lax methods of former days the Spanish steamships had been fertile sources of infection to the city, but now all the conditions were changed for the better.

On the Agency of Parasitic Vermin and Other Insect Pests in the Spread of Disease.—Dr. George Homan, of St. Louis, sent a paper with this title, which was read by Dr. Torralbas. He said that the trend of science in seeking the causes of disease was to scrutinize more narrowly the personal sphere of man, his domiciliary environment, and his relations to domestic animals—renouncing all speculative vagaries as unprofitable. The initial success was the discovery of the itch-mite, followed by the identification of trichina spiralis as a verminous parasite of potent morbific influence. The different capacities in which insects appeared as carrier, host, or progenitor of organisms or virus must be considered, the genus musca illustrating at least four ways of conveying disease. He spoke of the rôle of the mosquito as the asserted host of the malarial organism and its alleged agency in the genesis of yellow fever, but he thought that while this insect might be able to transmit both of these diseases, it was possible that malaria and yellow fever might be spread by other means as well. He next referred to boophilus bovis in its relation to Texas fever and the possible incrimination of other varieties of ticks in the propagation of disease in sheep, of rabies in dogs, wolves, etc., and to pulex in its probable relation to bubonic plague, and suggested its complicity in communicating the exanthemata. Other points considered were the influence of pediculi in disease, their prompt abandonment of bodies of the dead and dying being suggestive of ability to convey infection, and that of the bed-bug, which was deemed capable of spreading tuberculosis, syphilis, leprosy, carcinoma, and possibly bubonic plague. He thought that the aim of disinfection should be the destruction of vermin found in clothing, bedding, etc., for with their elimination danger from spores and germs would practically vanish. The necessity for the closest scrutiny of these insects and knowledge of all phases of their existence, he said, was obligatory on sanitarians.

The Tongue as a Breeding-Place for Bacteria.—Dr. M. H. Fletcher, of Cincinnati, read a paper on this subject, illustrated with a number of micro-photographs of sections of the tongue. He said that of the seven nutritive media for bacteria in the mouth, noted by Müller, there were always present on the tongue saliva, mucus, buccal epithelium, and particles of food. He noted the various conditions in which a coated tongue was present, and said he was in accord with Van Valzah and Nisbet in denying that "the tongue is a mirror of the stomach," as the older writers asserted, but held with the authors mentioned that it was solely an indicator of what processes were going on beneath and on its surface. He said that the micro-organisms in a dirty mouth, independent of those which might be introduced with the food, were sufficient in themselves to give rise to intense fermentation processes in the stomach, chronic dyspepsia, etc. He concluded with the statement that there was probably no means of estimating the degree of immunity that might be obtained by strict buccal cleanliness, but as a prophylactic measure no physician could afford to neglect it either for himself or for his patients.

The Benign Effects of the Climate of Cuba on Foreigners.—Dr. Enrique B. Barnet, acting assistant surgeon, U. S. A., read a paper with this title. He said his work was based on experience derived from the care of more than two hundred men, composing batteries H and N of the Second Artillery, and the Santa Clara battery. These men had been under his care for two entire years, and in that time he had had but two cases of pernicious malaria, eight of catarrhal dysentery, and four of yellow fever, none of these cases terminating fatally. He had had only two deaths during the two years, one in a soldier of rather advanced age who had heart disease, the other in a soldier who already had malarial cachexia and cirrhosis of the liver (possibly alcoholic) on his arrival in Cuba. This would seem to demonstrate that the stranger in Cuba, living under rational hygienic conditions, was no more exposed to the dangers of disease than he would be in the most healthful regions of the temperate zone.

Maritime Quarantine and Hygiene.—Dr. Rhett Goode, of Mobile, Ala., presented a paper dealing with the true function of quarantine together with the plan of enforcing it. His subject was divided into first, ships and cargoes; second, human beings and baggage. As regarded ship and cargoes, they should, he said, when from infected ports, be disinfected at either the port of departure or the port of arrival, and then be allowed to proceed to destination; human beings should be held at quarantine for five days, and their baggage should be disinfected, then if all was well they should be allowed to proceed. Special rules might be made to prevent a ship becoming infected at the port of departure, and when the ship obeyed those rules, she might be allowed to proceed. He thought a reclassification of the Latin-American ports, as regards their sanitary condition, was necessary, and in order that this might be done with justice to all rights concerned a competent commission should be appointed to do the work.

Period of Incubation of Yellow Fever.—Dr. Henry R. Carter, United States Marine-Hospital service, read a paper with this title.

Prevalence of Glanders in Havana among Horses and People.—Dr. Honoré E. Lainé, of Havana, said that during the last thirty years more persons had died of glanders in Havana than in all the large capitals of the world combined. The causes of this prevalence had been the ignorance of the people who, as a rule, did not fear the disease. This absence of fear was due to the erroneous teachings of the former Spanish veterinarians, who believed in the non-contagiousness of farcy. The prevalence of the disease was also the fault of the authorities, who had not exercised a scientific, rigorous, and honest inspection of the stables of

the city, in which to-day ten per cent. of the horses were suffering from glanders in its chronic form. Because of the mild climate of Cuba the chronic was the most prevalent and also the most dangerous form of the disease, as, that condition being compatible with life, the animals were made to work and in that manner spread the disease through all parts of the city and infected human beings as well.

The Service of Disinfection of Havana.—Dr. José Antonio López, of Havana, gave a history of the service under his charge. On April 1, 1899, when he was given the direction of the above-mentioned service, he found that it existed only in name, as neither its small force (five men) nor the apparatus at its disposal (ten pans and two worthless pumps) met the needs of the service. Under the authority of the chief sanitary officer, Dr. López proceeded to reorganize the sanitary corps, dividing it into a department of disinfection, and a department of sanitation. The department of disinfection had charge of the disinfection of houses where contagious disease had occurred, and the sanitary police was charged with the isolation of persons sick with such disease. The department of sanitation was charged with the cleaning of houses whose state of filthiness menaced the public health. The service at present consisted of more than two hundred and fifty employees, and had the necessary apparatus and instruments for the disinfection of houses in conformity with the teaching of modern science. Irrigation with a bichloride-of-mercury solution of a strength of 1:1,000 was used, also vaporizations of formol. There was also an oven for the disinfection of clothing. The speaker also detailed the methods employed in cases of yellow fever, typhoid fever, diphtheria, smallpox, and tuberculosis.

An International Commission for the Study of Yellow Fever.—Dr. Eduardo Wilde, minister of the Argentine Republic in Washington, presented a communication reviewing the arguments detailed in his address before the second general session, calling for the appointment of an international commission for the study of yellow fever and the devising of measures looking toward its extermination in all American seaports. At the close of his remarks he offered for the consideration of those present a resolution calling for (1) the convocation of an American international congress of hygiene, to be composed of delegates representing the various governments of America which might agree to this convention, the mission of which should be to draw up a plan for a general treaty in which should be noted the measures necessary and effectual for suppressing yellow fever in its endemic foci, or where it may have been imported and where the necessary measures of protection against this and other infectious diseases were not properly enforced; (2) to authorize the president of this third Pan-American Medical Congress to communicate with the several governments of the American nations, asking them to agree to those conventions and to nominate delegates to the congress of hygiene.

Dr. Porter, of Key West, said that he did not understand the language of Dr. Wilde's resolution sufficiently well to enable him to discuss it. But he would recall the paper presented at a previous session, at the conclusion of which he had presented a resolution which he would here repeat. He was greatly interested in the question of quarantine, especially as regarded yellow fever. For some years, he said, many had been groping blindly after a solution of this problem, and several commissions had been appointed from time to time to study the question, but they had been temporary commissions only. He now proposed the establishment of a permanent commission, the labors of which should be continuous, and which could establish the necessary laboratories and pursue the investigation in a careful and thoroughly scientific fashion. The following was his resolution: (1) That this section of maritime hygiene and quarantine recommends to the Pan-American Medical Congress now assembled in Havana the creation of an international commission of bacteriologists and quarantine officials of extended experience to study the question of yellow fever, its etiology, and mode of transmission; said commission to be appointed by the countries chiefly interested in the subject, its equipment and maintenance to be defrayed by the countries from which its members were appointed. (2) That this commission should report the detailed results of its labors to the next meeting of the Pan-American Medical Congress.

Dr. Holbeck, of Charleston, S. C., said that all present were interested in this subject. Everything possible had been done in the way of quarantine and disinfection, but yet almost nothing had been accomplished. Steam and other disinfectants were employed blindly, those using it being ignorant of what they were contending against. He thought this association should insist that only those most competent should occupy themselves with this subject. It was not solely a commercial but also a humanitarian question. He thought that all the interested countries should unite in this task; the work thus far done was praiseworthy, but it had led to no practical results; what was needed was the combined wisdom of many. All remembered the many years passed in ignorance of the true nature and mode of transmission of malaria, but now we could attack it scientifically—and this would be eventually the case with yellow fever. He criticised the present methods of disinfection, and thought a scientific body such as this congress should not hesitate to initiate a work of the kind proposed, and hoped that a commission would be established which might have something of practical value to report at the next congress.

Dr. Debayle, of Nicaragua, thought that the resolution of Dr. Wilde covered very nearly that of Dr. Porter. It was known that commissions of this sort took a long time in convening and beginning their labors, and in view of the work lately realized by the United States army commission, the wisdom of forming an international commission might be doubtful.

Dr. Santos Fernandez, of Havana, president of the congress, said that the propositions of Drs. Wilde and Porter were worthy of consideration, but he questioned their opportuneness, as no doubt the work of the proposed commission would, to a certain extent, be fully carried out by laborers already in the field before the commission could get together.

After some further discussion by Dr. Tamayo and others, it was decided to suggest to the various governments interested the formation of a commission after the plan and for the object noted in the two resolutions of Drs. Wilde and Porter.

The following papers were read by title: "Yellow-Fever Statistics of the Paula Hospital for Women from 1876 to 1900," by Dr. Jorge Le-Roy y Cassá, of Havana; "Public Turkish Baths," by Dr. Charles H. Shepard, of Brooklyn, N. Y.; "Restrictions on Typhoid Fever," by Dr. H. B. Baker, of Lansing, Mich.; "The Problem of Infected Well Persons," by Dr. C. V. Chapin, of Providence, R. I.; "Universal Vaccination in Porto Rico and its Results," by Dr. J. Van R. Hoff, U. S. Army; "Quarantine of Yellow Fever," by Dr. Narciso del Río, of Mexico; "Bovine Malaria," by Dr. Francisco Etchegoyham, of Havana; "The Present State of the Bacteriological Problem of Yellow Fever," by Dr. Antonio Matienzo, of Tampico, Mexico; "A Study of the Vegetable Parasitical Origin of Carcinoma, Confirming the Investigation of Dr. Brá," by Dr. Nicolas Carvallo and Frederico Torralbas, of Havana.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held February 11, 1901.

ROBERT F. WEIR, M.D., IN THE CHAIR.

Uterine Hemorrhage: its Cause and Significance.—The entire evening was devoted to a discussion of this subject.

Menorrhagia in Young Girls.—DR. W. GILL WYLIE said he had given this subject much study for a long time. Hemorrhage was one of the first symptoms calling attention to disturbances of the generative organs in young women. Frequently, especially among the better class of people, young girls had an interruption in the development of the genital organs through overwork, through brain-work, through social and school duties, which interfered with normal menstruation and later led to abnormal menstruation. The lives of young girls differed much from those of boys, and the generative organs of the former were much more important than those of the latter; particularly should girls be in as complete health as possible at those periods when troubles were more likely to arise. One of the chief points in the consideration of the significance of hemorrhage, he thought, had been overlooked. Frequently the general health of a young girl was badly affected and there was no menstruation; that was normal; an anæmic, weak girl should not be submitted to this drain. Again, it was a fact that if a girl was weak, anæmic, and imperfectly developed, and she menstruated, it was not a normal menstruation. Menstruation was really hemorrhage, so much so that it was often necessary to stop a normal flow. This point he brought out in a manual many years ago; before that time it had hardly been mentioned in literature. If a woman was weak and anæmic she should not menstruate. In anæmic women, especially in virgins, there was imperfect development; then the weak, anæmic, and feeble organs became a prey to disease; the endometrium became abnormal from catarrhal affections, resulting in excessive menstruation. A strong, vigorous girl might menstruate six or eight days and yet this might be a normal menstruation; in a weak girl this would not be true. Small fibroid tumors might exist for a long time without causing any hemorrhage; but when the growth impinged upon the endometrium it caused an increased vascularity, and so hemorrhage.

Metrorrhagia due to Neoplasms.—Dr. W. Gill Wylie also considered this topic. Among the interesting neoplasms found in young girls were fibroid tumors and, under twenty years of age, sarcomas. Malignant growths, such as carcinoma and epithelioma, as found in older women, were comparatively rare. The most important of all was a consideration of neoplasms occurring after the age of forty, when degenerative processes took place. Hemorrhage and the other abnormal symptoms occurring at the menopause were believed by many men and women to be normal manifestations of this period. He believed that many of these abnormal conditions would be discovered if these patients were to undergo an examination. Cancer of the uterus, if discovered in the early stages, offered better hope for cure from surgical intervention than cancer in any other organ of the body. Hemorrhage was one of the earliest symptoms. After the menopause the hemorrhage might occur so late that the disease had advanced to a great extent and intervention was too late to be curative. Almost always, if a woman menstruated after the age of fifty, it meant that there was present a fibroid, a polypus, or cancer. If she menstruated between the ages of fifty-two and fifty-four cancer should be suspected. If a woman ceased to menstruate and began again after a period of six months, one should be suspicious of some neoplasm. Early in life there might be a fibroid or polypoid form of tumor which was latent; as the patient grew older the discharge caused an irritation; the irritation caused a slight erosion that produced external bleeding which was frequently mistaken for one due to cancer. Any excessive hemorrhage occurring at or about the menopause was often attributed to this change and so these patients were not examined. If a woman flowed after the age of fifty the probabilities were that she had a malignant growth. This was the reason why so many cases of cancer of the uterus were brought to the gynæcologist in such hopeless condition. Another mistake made by many men was that they attempted to check the hemorrhage by tamponing, or else they cut out a piece to be sent for examination. It was a well-known fact that malignant growths should not be irritated. No pieces should be cut out unless the case was a very doubtful one. Such irritation caused congestion, and the pressure tended undoubtedly to cause the lymphatics or other vessels to carry cancerous material outside the field of practical surgery. In all cases of neoplasms with indications of malignancy, especially in the degenerated organs after fifty years of age, he advised a complete radical operation as early as possible.

Metrorrhagia due to Inflammatory Processes within the Pelvis.—DR. EDWIN B. CRAGIN continued the discussion. In treating metrorrhagia due to inflammatory processes within the pelvis, three factors must be considered: 1. The endometrium. 2. The muscular wall of the uterus. 3. The blood-vessels of the uterus.

1. The endometrium. The general rule held that, given a metrorrhagia, an endometritis should be expected. While it was generally recognized that endometritis might be either acute or chronic, and its origin either bacterial or non-bacterial, frequent bacteriological examinations of a uterine cavity the seat of a chronic endometritis had proved it sterile, and the endometritis of non-bacterial origin, in a very large number if not the majority of cases. It was acute endometritis, whose causation was assigned to pathogenic bacteria, introduced at various times and in various ways, at full-term parturition or the puerperium, at abortion or operation, by dirty fingers, dirty instruments, retained secundines, etc. While it was admitted that during an acute endometritis there might be at different times a muco-purulent discharge streaked with blood, an acute endometritis was of such short duration, and the metrorrhagia if present was so slight in amount, that we might practically dismiss acute endometritis as a common cause of metrorrhagia. With chronic endometritis, however, metrorrhagia was a common associate. A uterus with a normal muscle wall, normal uterine vessels, and a smooth endometrium usually implied normal menstruation and no metrorrhagia. A rough, hypertrophied endometrium implied menorrhagia, or metrorrhagia, or both. For the usual origin then of metrorrhagia we must look to a chronic endometritis and its causes. Although chronic endometritis might be the result of an acute endometritis of bacterial origin, certainly in a large number of cases it arose as a result of a chronic congestion in the same way that chronic inflammation followed chronic congestion in any other mucous membrane. As the uterus was situated between two viscera, one of which at least—the rectum—was often in a condition of distention, and as the uterus was prone to displacements from relaxation of its supports and increased weight, chronic congestion of the organ in general and of the endometrium in particular was easy to understand as a result of obstructed venous return. When we considered the situation of the uterus, in juxtaposition to Fallopian tubes, ovaries,

peritoneum, and cellular tissue often the seat of inflammation, chronic congestion of the endometrium, as a result of increased flow of blood to the part, was also easily understood. Chronic congestion of the uterus the result of disease of distant organs was to be discussed by other speakers. In his opinion the usual order of source and sequence was, chronic congestion of the endometrium, chronic inflammation of the endometrium, menorrhagia, and metrorrhagia.

2. The muscular wall of the uterus. No one who observed carefully, during parturition, the action of the uterus in controlling hemorrhage, could fail to realize that on the contraction of the irregularly arranged fibres of the muscular wall depended the amount of blood flowing through and from the uterus. If this contraction was normal and unimpeded, the circulation of the uterus and the loss of blood from the uterus were normal. If the contraction of the muscular wall was in any way interfered with, the amount of blood flowing through and from the uterus was abnormally increased. This same relation of muscular contraction and blood flow held, in the opinion of the writer, in the non-pregnant uterus, and anything interfering with the normal contraction of the uterine muscle, other things being equal, favored an excess of blood flow through the uterus, with menorrhagia and metrorrhagia. The two conditions most commonly interfering with normal contractions of the uterine muscle in the non-pregnant state were (1) tumors of the uterine wall and (2) chronic interstitial inflammation of the uterine wall, in which there were atrophy of the muscular tissue and an increase of new connective tissue. Although both of these conditions most often produced metrorrhagia through the medium of a chronic endometritis, occasionally one met with cases in which the endometrium seemed but slightly involved and the bleeding seemed to be caused by a lack of sufficient elasticity in the uterine muscle, due to interference with the normal muscular contraction.

3. The blood-vessels of the uterus. In the same way that interference with the normal muscular contraction of the uterine wall favored an excess of blood in and passing from the uterus, so interference with the normal contraction of the arteries themselves favored the same results. Occasionally, especially in the later part of menstrual life, and often associated with the two conditions just discussed, viz., tumors of the uterine wall and chronic interstitial inflammation, the vessels of the uterus were found in a condition of arteriosclerosis, with insufficient elasticity either to maintain the normal balance of uterine circulation or to check the flow beginning at a menstrual period. Here again, although this inflammation of the arterial wall usually produced metrorrhagia through the medium of a chronic endometritis, occasionally cases were met with in which the endometritis was slight, or did not respond to the use of the curette, and the hemorrhage seemed due to the lack of contractile power in the arterial wall.

The question of the treatment of metrorrhagia depended very largely on its etiology. As the most usual immediate cause was a chronic hypertrophic endometritis, curettage followed by endeavors to relieve the chronic congestion was usually the best treatment. When due to acute endometritis, cleanliness, drainage, and rest usually gave the best results. The treatment of metrorrhagia due to interference with the muscular contraction of either the uterine wall or the uterine vessels depended upon the presence or absence of an hypertrophied endometrium. The presence of the latter indicated curettage, perhaps several times repeated. Metrorrhagia, with an absence of hypertrophied endometrium, or persistent after repeated curettage, might justify hysterectomy.

The Causes and Significance of the Obstetric Hemorrhages.—Dr. J. Clifton Edgar divided this subject into three divisions:

I. The metrorrhagia of pregnancy: ante-partum hemorrhages.

Uterine hemorrhage, moderate or severe, occurring during the forty weeks of pregnancy naturally suggested to our minds the six queries: 1. Was it a simple abortion or miscarriage? 2. Was it a case of placenta prævia? 3. Was it a premature separation of a normally situated placenta (accidental hemorrhage)? 4. Was it one of ectopic gestation? 5. Was it a traumatic or spontaneous rupture of the uterus? 6. Was it menstruation occurring during gestation? These were the principal etiological factors in ante-partum hemorrhage; still it should always be remembered that the diagnosis must be confirmed by a careful consideration of the symptoms and signs present, since we observed, although less frequently, ante-partum hemorrhage due (1) to the fever and local hyperæmia of the exanthemata, as variola, scarlatina, and measles; (2) to conditions of the heart, liver, and abdominal viscera producing obstructed venous return; (3) to hæmatosalpinx; (4) to sarcoma, fiboma, and polypus of the uterine body; and (5) to polypus and epithelioma of the cervix. Less frequently ante-partum hemorrhage, local in character but non-uterine in origin, had been mistaken for one of the six main causes stated. These hemorrhages, usually slight in amount, came (*a*) from the urethra, due to cause in the urinary tract; (*b*) from rupture of vaginal or vulval varicose veins; (*c*) from cancer of the vagina or vulva; (*d*) from anomalies of the intestines or anus, a common one being hemorrhoids. Most frequent and most important of the ante-partum hemorrhages was the bleeding indicative of a threatened or inevitable abortion which was due to a partial separation of the fœtal structures before the complete formation of the placenta. All the manifold and varied causes of abortion and miscarriage had to do with this variety of hemorrhage. The possibility of menstruation continuing into pregnancy must also be granted. While it was true that menstruation was nearly always suspended during the whole period of gestation, recurring again six or eight weeks after the birth of the child, still exceptions to the condition of suspended menstruation in pregnancy occurred now and then during the early months, and were explained by the fact that the uterine cavity was not obliterated by the fusion of the decidua reflexa and vera until the close of the fourth month. In case the menses continued throughout pregnancy, a very rare condition indeed, there was probably an abnormal and incomplete fusion of the deciduæ. Some cases had been reported of women who menstruated only during pregnancy. Such reports should be carefully criticised, as such cases probably depended, without exception, on pathological conditions of the cervical canal. From an examination of a large number of membranes and placentas, the result of interruptions of pregnancy in the third, fourth, fifth, and sixth months, he was convinced that hemorrhage due to a low situation of the placenta was much more common than was usually supposed. By this he meant that a large proportion of the supposedly simple abortions and miscarriages were really instances of the implantation of the placenta in the lower uterine segment, with resulting hemorrhage and evacuation of the uterus as a consequence of partial separation of the abnormally situated placenta, due to changes in the shape of the lower uterine segment dependent upon the growth of the uterus. It was generally thought and usually taught that hemorrhage from a placenta prævia did not show itself until the twenty-eighth or thirty-second week of gestation. In his collection he had a uterus with the fœtus and membranes intact, and a central placenta prævia, from

a woman who died within a few hours of the first hemorrhage at the sixteenth week of pregenancy. A careful autopsy showed that death was due to the acute anæmia produced by the hemorrhage from the partial separation of the central placenta prævia. He was further convinced that a careful study of the site of rupture of the membranes, in instances of supposedly accidental hemorrhage, would prove that hemorrhage during pregnancy and also during parturition, from the premature separation of a normally situated placenta, was a very rare condition indeed. He had found several cases of supposedly accidental hemorrhage that were really those of lateral placenta prævia, a more complete examination after fuller dilatation, and the examination of the rupture in the membranes post partum, indicating the condition that caused the hemorrhage. Severe hemorrhage from the partial separation of a normally situated placenta he believed to be very rare. Severe hemorrhage from a low implantation of the placenta he believed to be much more common than was generally supposed.

II. The metrorrhagia of labor: partum or intra-partum hemorrhages.

1. Of the first and second stages. These were principally due to (*a*) premature separation of a normally or abnormally situated placenta; (*b*) to ruptures of the uterus or cervix; and (*c*) to fibroid tumors, malignant disease of the genital tract, or rupture of varicose veins.

2. Of the third stage. Here, first and foremost, stood (*a*) uterine inertia as the most important etiological factor, uterine inertia occurring with a partial or complete separation of the placenta. Next in importance came (*b*) laceration of the genital tract, namely, of the lower uterine segment, the cervix, vagina, and perineum. Another important cause was (*c*) insufficient contraction of the lower uterine segment in cases of low implantation of the placenta. Here, while the fundus contracted firmly and completely, an imperfectly contracted lower segment permitted of fatal hemorrhage from the open blood-vessels of the low situated placental site. (*d*) Partial or complete inversion, although a most infrequent cause, must be enumerated and the likelihood of fibroids of the uterus or cancer of the genital tract must be borne in mind.

III. Puerperal metrorrhagia proper: post-partum hemorrhages. Puerperal hemorrhages were those occurring from six hours after the completion of the third stage of labor until the completion of the normal period of involution, namely, six weeks. These hemorrhages depended almost wholly upon the proper management of the second and third stages of labor and the care the woman received during the first few hours or days of the lying-in state. The amount of lochial discharge varied in different women. In some it always continued longer and was more abundant, yet not enough to justify us in calling the case one of secondary post-partum hemorrhage. As in intra-partum hemorrhages so in post-partum, the hemorrhage might come on in so sudden and so unexpected a manner that there would be no premonitory symptoms of the accident, the external flow of blood being the first symptom.

The causes were general and local. Among the general causes were (1) mental emotions, as shock, anger, fright, fear; (2) disturbance of the general circulation, as from the abuse of stimulants, the excessive use of chloroform, certain conditions of the heart and liver that interfered with the return circulation; (3) certain blood conditions, as extreme malarial poisoning, albuminuria, and puerperal sepsis; (4) the acute infectious diseases. Among the local causes were (1) anything which interfered with the proper contraction of the uterus during the puerperium, as (*a*) retained blood clots, portions of placenta or membrane: (*b*) a secondary placenta; (*c*) a distended bladder or rectum; (*d*) retroflexion; (*e*) inversion; (*f*) fibroid or polypoid tumors; (*g*) cervical lacerations; (*h*) malignant disease of the uterus; (*i*) simple subinvolution. (2) Causes inducing pelvic hyperæmia: (*a*) assuming of the upright position too soon after delivery; (*b*) too early sexual intercourse. (3) Thrombi which closed the uterine sinuses might be dislodged by sudden exertion, or by septic processes in uterine phlebitis.

Uterine inertia or relaxation as a cause of hemorrhage after the third day of the puerperium was of rare occurrence. Retained blood clots were more frequent in multiparæ, and might be usually prevented by careful attention to the uterus during the hour following the completion of the third stage, known as the "physician's hour." Hemorrhage from retained placental fragments and membranes was due to an incomplete third stage, and might be prevented by careful examination of placenta and membranes at the time of expulsion and removal of retained fragments. The retention of small pieces of membrane did not necessarily produce puerperal hemorrhage or other complications.

Uterine Hemorrhages due to Organic Diseases in Other Organs and to Constitutional Disturbances.—Dr. Andrew H. Smith discussed this part of the topic. Diseased conditions in other organs of the body might result in obstructed circulation, as in cases of heart disease when the valves were insufficient and an unnatural strain was placed upon the veins of the uterus. The same might occur in connection with any obstruction to the blood flow through the liver. Those women who were subject to hemorrhoids he thought were likely to have excessive menstruation from the fact that the return of blood through the uterine plexus was very similar to that through the lower portion of the hemorrhoidal plexus; in both cases there was a free communication between the portal circulation, and any obstruction of the circulation through the liver reacted upon the circulation of the uterus in the same way that it did upon the circulation in the lower portion of the rectum. Women who were chronic sufferers from hemorrhoids were very likely to suffer, other things being equal, from excessive menstruation. Abdominal tumors, by pressing upon the abdominal veins, caused changes in the mucous membrane of the uterus which predisposed to hemorrhage. Uterine hemorrhages depending upon constitutional disturbances were due to some change in the flow as well as to a change in the blood itself. Hemorrhage from the uterus associated with syphilis was due to degenerative changes in the vessels. Also, we had changes in the blood itself which tended to permit leakage and escape of blood from the vessels. as in anæmia. In the early grades of anæmia, in which it was not pronounced, there was but a slight inclination to the escape of blood on account of the thinness of the blood; but later on, when the anæmia had reached a more pronounced grade, there was produced rather an amenorrhœa. because there was not sufficient vitality to excite the uterus to the usual menstrual flow; in other words, in the early stages of anæmia we might have menorrhagia or metrorrhagia, while in the later stages we were apt to have amenorrhœa. In purpura hæmorrhagica we had a condition of the blood and blood-vessels which favored the escape of blood, and not uncommonly we found an undue flow of blood from the uterus. In scurvy and scrofula the same state of affairs seemed to be produced. The eruptive diseases were also accompanied by excessive menstruation. In typhoid fever there was a form of hemorrhage called the "uterine epistaxis." Great debility from prolonged lactation also produced this trouble,

probably by inducing anæmia. There was another class depending upon emotional troubles, and just what was the condition here produced he did not know. Frequently we saw an arrest of menstruation, sometimes a permanent one, a premature menopause excited by some very great fright or other emotional disturbance. In all these cases the matter of treatment was involved in the treatment of the systemic condition on the one hand and that of the diseased organ on the other.

Placenta Prævia.—Dr. Edward A. Ayers said that Leopold had helped somewhat in lessening the difficulty of recognizing the location of the placenta at the lower segment of the uterus; he had found after Cæsarean section that the uterus had a marked tendency to expand at the portion covered by the placenta, and he demonstrated that the traction of the Fallopian tubes and ovaries was posterior when the placenta was attached to the anterior portion of the uterus, and *vice versa*. When the placenta was attached to the lower segment there was a certain increase in thickness and a boggy sensation was imparted. But, after all, it was difficult to determine this location. Any hemorrhage occurring should suggest some form of placenta prævia. In the early periods the hemorrhage was caused by changes in the chorion. He recalled one case of hemorrhage occurring at the eighth week. There were three successive attacks at intervals of several months. At the delivery ciactricial tissue was found at the periphery of the placenta, showing that the hemorrhage had occurred at this point.

Management of placenta prævia. The best methods of procedure were those that aimed at obtaining a living child. Four methods were to be considered: (1) The use of the tampon in the vagina. (2) The use of the hands—manual dilatation. (3) Garrigues' bags. (4) Barnes' bags. He favored the Barnes' bags. In using the tampon we were uncertain as to what was occurring, and this was unsurgical. In manual dilatation we were obliged to occupy from fifteen minutes to an hour in securing dilatation, and it was almost impossible to do it without the hemorrhage continuing. Garrigues' bag was an inverted cone, and separated the placenta at the start. The process by manual dilatation required more time than was consumed in the use of the Barnes' bags. Barnes' bags began by stretching the internal and external os and the cervix between, and did not separate the placenta to the same degree. The left hand in the vagina held it in place, and if we used the double stop-cock we could lessen the tension and could secure as much dilatation as was necessary to bring down the leg and get the child within the cervix, practically without any hemorrhage at all. He was satisfied with this method.

Dr. J. R. Nilsen said that normal menstruation was under the control of two groups of forces, the inceptive and the desistive. Under the influence of the first, ovulation and menstruation were initiated. Menstruation continued from two to four or five days, and then ceased not only because of spent inceptive forces, but through influences from new desistive forces acting in a great measure through the vasomotor system. There was a numerous class of women whose menstrual period was ushered in promptly, with little or perhaps no suffering, but who continued to flow five, eight, ten days and even more; this constituted hemorrhage. As far as instrumental interference went it was largely a let-alone class, for there might be no local disease whatever to call for interference. The flow finally ceased only because so much had been lost that there was no longer enough for sufficient pressure in the vessels to effect further transudation, or the flow was so poor and thin that clots were not formed in the ruptured capillaries, or else the desistive forces were incapable of establishing normal muscular contractions in the uterus and in the vasomotor system concerned. The causes were constitutional, for the blood was poor and the muscular system throughout was sluggish.

The first thing demanding attention was the saving of the precious fluid by promoting, artificially, a reaction and stimulating the desistive forces. This could be done by judicious packing applied as carefully as possible under the broad ligaments. He did not allow such patients to flow many hours, and while preventing the drain began at once general systemic treatment. The effects were very gratifying. He advised against curetting the uterus unless we knew positively just what the cause of the hemorrhage was. He referred to another class of patients, and urgently advised never to pack but always to use the curette. A patient gave a clear history of recent abortion, with continuous flow since, having always menstruated normally before. There was no elevation of temperature and no evidence of disease anywhere in the pelvis, only some tenderness about the uterus. Packing should be avoided, except only to dam back the blood until the curette could be used. He claimed that he had evidence that many general practitioners were packing the uteri under these conditions, and this should be discouraged. Some fragments of the ovum had been left behind, attached over an area where involution in consequence was prevented, and some only half-occluded sinuses kept on bleeding. These fragments were usually found high up in one of the horns near the Fallopian tube, and they should be removed. Only the area holding these fragments should be curetted, using absolute asepsis and a sharp curette. It was rarely necessary to dilate. The curette should be held like a pen, and with hardly more than its own weight the operator should feel his way over the surface of the endometrium. He would come from the smooth, non-bleeding surface upon a rougher spot and would appreciate the mass situated there. The curette should be passed over and just beyond it, and then the sharp edge should be pressed down and the mass scooped outward. The reason that the fragments were found up in the horn was that, after ovulation, the ovum emerged from the Fallopian tube and attached itself to the first fit place and, in a perfectly normal uterine cavity, received a ready welcome immediately upon its entrance. At the abortion the muscular ring forming the horn contracted and clutched a portion of the placenta, holding it tightly, while the rest of the ovum was torn from it and expelled.

Dr. Edward E. Tull believed that uterine hemorrhage was present so often that it was not quite characteristic of anything except in certain conditions, as for instance extra-uterine pregnancy. He had never seen a case of this in which hemorrhage did not exist, and therefore it should be considered a strong factor in making the diagnosis. Hemorrhage due to anæmia was often encountered and would be benefited by liberal doses of iron.

Dr. Abram Brothers thought that the term irregular uterine hemorrhage should be used to designate these hemorrhages, whether menorrhagia or metrorrhagia, whether due to some pathological condition which produced the symptom of bleeding, or whether the bleeding was in the form of a protracted or irregular flow during intermenstrual periods. He was glad that the question of type had not been referred to, for his experience had taught him that there was but one normal type, the four-weekly type. Irregular uterine hemorrhages were usually accompanied by some underlying pathological condition, some chronic congestion of the uterine mucosa, or inflammation. Amenorrhœa and irregular uterine bleeding might often be overcome in young girls simply by the administra-

tion of tonics and attention to hygienic surroundings. One week ago he was called to see a case of supposed placenta prævia. The patient was believed to be seven months pregnant and she had had a fearful hemorrhage. He found the patient had been tamponed, and was still bleeding through the tampon. Upon removal of the latter he received in his hand a fœtus one and a half inches long. This woman had a three-months' fœtus, for four months dead, within the uterus, and there was nothing in her condition to show that she was not seven months in normal pregnancy. Ectopic gestation was a subject of great importance; the causes of bleeding in this condition were frequently overlooked. Hæmophilia, as a constitutional cause of uterine hemorrhage, he briefly referred to. Malignant disease was to be looked for not alone in women of forty, fifty, or sixty years old: he had treated malignant disease of the breast in a woman of twenty-four, and he also had had occasion to remove a cancerous uterus by vaginal hysterectomy from a woman of twenty-six. Persistent hemorrhages not relieved by the curette called for vaginal hysterectomy.

Menorrhagia.—Dr. Austin Flint, Jr., referred to cases of excessive hemorrhage in which it had been found necessary to tampon the vagina at the menstrual epoch; one occurred in a case of hæmophilia, another in a case of membranous dysmenorrhœa. Both cases had been repeatedly curetted without benefit.

Dr. W. Gill Wylie said the tampon had been much abused in the past and was still abused by many men, and he disliked to recommend its use except in such cases as those referred to by Dr. Flint. It took an expert to stop hemorrhage by this means. If the hemorrhage was stopped it distended the uterus, and was then forced back into the Fallopian tubes, distending them—especially in cases of hemorrhage occurring at a time when the Fallopian tubes were enlarged, as with miscarriages, labor, or fibroids. In this way might develop cases of cellulitis and of local peritonitis. In his service at Bellevue hospital, in twenty years the tampon had not been used three times. The uterus should be dilated and the cause of the hemorrhage gotten rid of, and the bleeding would always be stopped.

Therapeutic Hints.

Cough (acute or chronic).—

℞ Oil of wintergreen ..... ℥ ij.
Oil of cinnamon ..... ℥ ij.
Hydrocyanic acid (dilute) ..... ℥ iiss.
Glycerin ..... ℥ v.
Simple syrup ..... ℥ x.
Water ..... ℥ xxiv.
Irish moss ..... ʒ ss.
Linseed oil ..... ℥ xv.

Make an emulsion. Give two to four teaspoonfuls three times a day.

—Wm. H. Thomson.

When the cough is very irritating or painful codeine gr. $\frac{1}{6}$ may be added to each dose with advantage.—*Merck's Archives.*

In Eye Practice.—Large doses of potassium iodide are indicated in optic neuritis, ocular paralysis, choroiditis, serous iritis, relapsing iritis, cyclitis, and interstitial keratitis.—Albert R. Baker.

A Stable Solution.—

℞ Cocainæ hydrochlorat ..... gr. iv.
Aquæ destillat ..... ℥ iiss.
Acidi salicylici ..... gr. $\frac{1}{6}$
M.

—*Jour. de méd. de Paris.*

Sciatica.—Much attention should be paid to diet. Food should be liquid and nourishing and given frequently in small quantities. Hot milk is one of the best forms. Home-made broths and preparations of blood are useful. The rectum should be flushed every day or every second day with large quantities of hot water.—A. P. Williamson.

Coryza.—Local treatment for coryza is essential after the contraction of the cold. In making such local applications the nasal mucous membrane should first be slightly sprayed by a two-per-cent. solution of cocaine, a very few whiffs from an atomizer. Then the nose should be thoroughly cleansed by spraying with Dobell's solution, the head being tilted backward to allow the solution to cover completely the floor of the nose.—H. B. Wood.

Heroin.—Heroin and heroin hydrochloride can be used with very good results in all disorders of the respiratory organs; they combat the cough and dyspnœa, the most troublesome symptoms of these disorders. In hæmoptysis they will often check hemorrhage when other remedies fail. To avoid unpleasant after-effects, which are very rare in adults, heroin should be given always after meals. Heroin is also a very valuable drug in diseases of children, but the dose should be as small as possible, an overdose being liable to produce serious consequences. Heroin should be tried in whooping-cough, being of decided benefit in many cases, reducing the number of attacks, or at least influencing their duration and severity. Heroin and heroin hydrochloride, especially the latter, when used hypodermically, act promptly in bronchial asthma.—I. J. Martinson, *The Medical Times*, January, 1901.

Incontinuence of Urine.—

℞ Extr. fluid. rhois aromat ..... gtt. v.–xx.
Syr. aromat ..... gtt. xx.
Aq. destill ..... q.s.
S. One dose t.i.d.

—Perlis.

Cardiac Stimulant.—

℞ Caffein.,
Sod. salicyl ..... āā 1–1.5
Spartein. sulph 0.40
Amm. acetat ..... 1.
Aq. destill ..... 50.
M. S. ʒ i. every half-hour p.r.n.

℞ Caffeinæ,
Sod. salicyl ..... āā 2–2.50
Spartein. sulph 0.50
Aq. dest ..... q.s. ad 10 c.c.
M. S. Inject gtt. xx. subcutaneously.

—Capitan.

Epileptic Attacks may be averted by preventing the aura to reach the central nervous system. To accomplish this a towel is tied tightly around the extremity in which the aura or creeping sensation is first felt.—Kovalewski.

Asthma.—A good combination for general use internally is the following:

℞ Sodium iodide,
Sodium bromide ..... āā gr. ij.
Fl. ext. euphorb. pil.,
Ethereal tinct. lobelia ..... āā gtt. iij.
Nitroglycerin ..... gr. $\frac{1}{200}$
M. S. Take at one dose, and repeat in half an hour, if needful.

In "cardiac asthma":

℞ Strych. sulphat ..... gr. i.
Morphin. sulphat ..... gr. i.
Tinct. digitalis ..... ℥ iv.
Aquæ ..... ad ʒ vi.
M. S. Teaspoonful every two to four hours or until the heart acts regularly.

—Jackson.

Hiccough.—Apply a bandage tightly around the body.—Jelks.

Alcoholic Mania.—

℞ Chloralamid ..... gr. xv.
Hyoscin. hydrobrom ..... gr. $\frac{1}{100}$

Neuralgia of the Face.—

℞ Butyl chloral hydrate,
Spt. vini rect. ..... āā ʒ iiss.
Glycerini ..... ʒ v.
Aquæ ..... ʒ iij.+ ʒ vi.
M. S. A teaspoonful once or twice daily.

Cough in Phthisis.—

℞ Codein ..... gr. iss.
Terpin. hydrat ..... gr. xv.
Ext. hyoscyami ..... gr. iss.
Ext. belladonnæ ..... gr. $\frac{3}{4}$
Mas. cyroglossi ..... gr. viiss.
M. ft. pil. No. x. S. One four times daily.

Insomnia in Melancholia.—A very hot bath at night with mustard in it will often break the sleepless habit.

Epilepsy.—The treatment by bromides should not be interrupted for one day during two years unless for some very valid reason, such as a febrile affection, and even then, if slight, the dose should only be diminished or, if suspended, should be recommenced when convalescence sets in. The menstrual period is not an obstacle, nor is pregnancy. On the contrary, the bromides would have a favorable influence on the fœtus.

℞ Bromide of potassium ..... 40 gm.
Bromide of sodium ..... 12 "
Bromide of ammonium ..... 12 "
Benzoate of sodium ..... 12 "
Water ..... 1,000 "
Each tablespoonful represents 1 gm. of bromides.

—Gilles de la Tourette.

Plasmon is an albumen preparation containing a very high proportion of nitrogen, and is extremely digestible. As practical trials have demonstrated, plasmon can replace all other albumen foods, and it is superior even to meat in nutrient value. Plasmon, moreover, can maintain the physical strength of workmen engaged in the most laborious tasks, and, therefore, at its low price, can be thoroughly recommended as of inestimable value as a food for the working classes.—Virchow, *The Medical Press*, October 10, 1900.

Thyroid Medication.—Tachycardia, nervous symptoms, loss of weight, etc., are largely obviated by giving arsenic coincidently.—Mabille.

Convulsions.—

℞ Calcii sulphat. ..... 0.06 cgm.
Aquæ ..... 250. gm.
M. S. Teaspoonful every hour for infants up to six months of age.

From the age of six months to a year the quantity of the sulphate can be increased to 15 or even 30 cgm. —Kinggs, *Bul. gén. de Thér.*, February 28th.

Premenstrual Pains.—

℞ Codein ..... 0.05 cgm.
Chloral ..... 1. gm.
Ammon. brom ..... 1. "
Aq. camph ..... 30. "
—*Presse méd. Belge.*

Nervous Insomnia.—

℞ Paraldehyde ..... 10 gm.
Spt. vini rect. (ninety per cent.) ..... 45 "
Syr. simp ..... 60 "
Tinct. vanillæ ..... 2 "
Aquæ destil ..... 30 "
M. S. Teaspoonful every half-hour for three or four doses during the evening.
—*Journ. de Méd.*

New Instruments.

A NEW INSTRUMENT FOR THE PROSTATE: FOR MASSAGE, INUNCTION, AND THE APPLICATION OF ELECTRICITY COMBINED.

By ROBERT COLEMAN KEMP, M.D.,
NEW YORK.

I am well aware that there are numerous excellent instruments for prostatic massage and many devices for the application of ointments per rectum. There are also electrodes for treatment of the prostate or intestines. I have been unable to discover, however, after careful investigation, an instrument which combines these three features in one. The advantages of such are manifest since frequent manipulation of the parts are thus avoided.

The instrument can be readily understood from the illustration. It consists of a metal tube about six inches long, insulated with hard-rubber to about half

an inch from the tip. This last is closed at its extremity, is given a slight prostatic curve, and has four perforations on its concave surface at B, for ointment or medicated solution to enter the bowel. The piston is a solid metal rod, fitting snugly the metal barrel of the instrument. It has an insulated handle of convenient length, about four inches, and at A is a binding post to attach to the pole of a battery.

Suppositories of ichthyol, etc., combined with lanolin are useful. Simple ointments can be so employed or antiseptics suspended in oil. They do not seem to interfere with electrical action, but to be absorbed more rapidly, probably due to the local stimulating effect on the circulation. This is not cataphoresis.

I have secured favorable results in a case of spasmodic stricture at the neck of the bladder. One patient with enlarged prostate, chronic cystitis, and dilated bladder, who for a year and a half has been able, with extreme effort, to void only a few drops of urine at a time, after each application of electrical massage voids from one-half to three-fourths of a cup of urine. This would seem to me rather suggestive, that if in the early stage of this condition electricity were more frequently employed, it would be a valuable adjunct in prolonging the functions of the bladder by increasing its muscular tone, and stimulating the detrusor urinæ muscle. In the cases treated up to the present time, I have used a mild faradic current, one pole (my instrument) in the rectum at the posterior margin of the prostate, and the other pole on the perineum, anteriorly. Massage and inunction were also combined. I would state that the diameter of the instrument is considerably less than that of the average index finger. By measurement, the diameter of the tube is $\frac{7}{16}$ of an inch. It was made by the Reynders Instrument Company, Twenty-third Street and Fourth Avenue.

Indications for Paracentesis of Membrana Tympani.—1. Great pain, with bulging of the membrane from contained pus; 2. When the tension of the membrane is high and the bulging even slight; 3. Insufficient drainage through a membrane already ruptured, and danger of extension to the antrum; 4. Excessive and continued pain which is not relieved by hot applications, especially if the tension be very high.—Randall.

Medical Items.

Action of Saccharin on Digestion.—From experiments performed by Nencki, he is of opinion that the use of saccharin in food need not be objected to, since he finds that saccharin used in quantities equal to a given sweetness produced by sugar, has less effect on the peptonizing of albumen than its equivalent of sugar.

Treatment of Lupus with Thyroid Gland.—J. J. Pringle in a clinical lecture (*Polyclinic*, September, 1900) advocates the use of thyroid tablets in the treatment of lupus vulgaris. He quotes two cases claimed as positive cures. One was that of a boy aged fifteen, with lupus of the nose, causing enormous swelling; after three years he was completely cured. The other case was that of a boy of eighteen with lupus of the thumb; he was cured in two months. Other cases are quoted in which much improvement took place, sometimes with the aid of scraping. If cases are going to improve with the thyroid, they generally do so within two weeks' time. In concluson Pringle is of the opinion that thyroid treatment is a valuable adjunct in the treatment of lupus when excision or erasion is not applicable. He thinks it presents advantages over the tuberculin treatment, the *x*-ray treatment, and possibly the Finsen light treatment. The dangers of thyroidism have probably been exaggerated. The best cases for this treatment are the acute suppurative tuberculous processes of the "scrofulodermatous" type and it is applicable in many cases in which surgical procedures are not feasible. It may be of use in the most chronic cases by preventing the spread of the disease and by preventing ulcerative attacks which often occur at certain seasons of the year. It may finally be useful as an adjunct to surgical treatment in preventing relapse.—*Treatment.*

Taking a Census.—The London *Evening Standard* says: "It was felt that the approaching end of the nineteenth century afforded a suitable opportunity for the different governments to come to an understanding, with the object of proceeding simultaneously to a universal census of the populations. The utility of such an agreement stands in no need of demonstration, and the value of an enumeration taken in an identical form, as regards all important features, may also be admitted without question. Unfortunately this ideal could not be arranged, but we are treated to the spectacle of a census in quite a number of the leading countries. In the Netherlands it was taken on the last day of 1899; in Portugal on January 1st last; in Denmark on February 1st; in the United States it has just been finished. In this month both Germany and Switzerland will proceed to 'the numbering of their peoples' and on the last day of this year Austria, Belgium, Hungary, and Sweden will follow suit. In Norway, January 1, 1901, is the day appointed; in Great Britain and Ireland, April 5th next; in France, April 12th, and in Italy, December 31, 1901. The system of an enumeration of a nation's people, its statistics of wealth and general progress in their various items, has only crystallized into a fixed policy within a hundred years, but the 'numbering of the people' is a very antique institution. The most ancient statistical records of the kind are those of Moses in the wilderness 1490 B.C. and later of David 1017 B.C. There is a record of a census in China ordained by the Emperor Yee in 2042 B.C., and one in Japan under the Mikado Sujin in the last century before Christ. The Greeks appear to have had a regular census system. In Attica an enumeration was said to have been made 317 B.C., and in Athens the citizens were divided and registered into four classes, according to the amount of their taxable property or income. In Rome, 500 B.C., every citizen had to appear on the Campus Martius, and declare in solemn manner his name and dwelling, the number and age of his children, and the value of his property, under penalty of having his property confiscated and of being scourged and sold as a slave. The Emperor Augustus had the people numbered, and he improved the method of doing it. In the Dark Ages, in fact from about A.D. 500 until A.D. 1700, there is no record of such work among the nations. The modern system of recording the evolution of the population was the outgrowth of the sixteenth-century practice of keeping registers of births, marriages, and deaths."

Thirtieth Annual Report of the Central State Hospital of Virginia.—This report has just been published and from a perusal of the same the impression is gained that affairs in the institution are on the whole in a satisfactory condition. At the termination of the fiscal year, September 30, 1900, there remained in the hospital 427 men and 441 women, total 868. One hundred and thirty-five patients were received during the year, 117 of whom were first admissions. The percentage of recoveries, based on the number admitted, was 43.5—37 for men and 50 for women. The death rate was exceptionally small, only four and one-half per cent. on the total number treated—this result reflects great credit on the medical and general management of the hospital. In nearly every case death was due to an incurable disease and but two were caused by tuberculosis, evidently owing to the greater preventive measures and sanitary precautions that have been taken in recent years. The industrial system is carried out thoroughly in the Virginia State Hospital, with beneficial effects both to the health of the patients and to the welfare of the institution. A most commendable alteration has been made in the "lunacy laws" of Virginia and one which might with advantage be followed by other States. Instead of three justices of the peace constituting the commission to adjudge one insane, as was formerly the case, the commission is composed of two physicians and a judge or justice. This is in the line of common sense and has already had a markedly good influence on the admissions to the hospitals in Virginia. The law requiring presidents of the respective boards and the superintendents to meet annually at one or other of the hospitals for consultation, exchange of views, etc., should also work well. The financial state of the Virginia Hospital is healthy, the annual per capita cost of each patient being the moderate sum of $92.90, while there remains to the credit of the establishment after all expenditures $3,183.52. Dr. Drewry, the superintendent of the Central State Hospital, Virginia, wrote a pamphlet in the spring of last year in which he complained that owing to the great increase of insanity in Virginia the accommodation in the State hospitals was quite inadequate. He then stated that within the first two years up to the time he wrote, 182 colored and many white insane had died in jails or at their homes while waiting for vacancies to occur in the hospitals. This reproach will shortly be removed from Virginia, as the new building in connection with the State hospital authorized by the legislature is approaching completion. With this additional accommodation the State will be in a position to take care of all the colored insane for the next two or three years. This is satisfactory, so far as it goes; but, as has been urged on every possible occasion in the RECORD, not only should there be ample provision found for those who have been adjudged insane, but hospitals should be established in every State in which should be temporarily deposited

suspected cases for the purpose of careful investigation by experts. Judicious, humane and intelligent treatment in the early stages of the malady will often go far toward curing its victims, while if a contrary course be followed the result will be that the disease will become incurable and chronic.

Etiology of Typhoid.—Plague and typhus we look upon as air-borne, typhoid and cholera as water-borne diseases. But these terms are only relative. If malarial fevers may under certain conditions become water-borne, it seems equally clear from the observations of Sir Charles Cameron, of Dublin, that typhoid may frequently be air-borne. Sir Charles' long experience of that typhoid-stricken city leads him to believe that the rôle which water plays in the distribution of the disease, though considerable, does not seem to be quite so great as is generally believed. Local epidemics he considers may be sometimes due to infected water or milk, to vegetables from infected soil, and to other similar sources; but in view of the fact that Dublin has the best water supply in the world and that the establishment of this water supply was not followed by any diminution of typhoid, he cannot admit that the general prevalence of typhoid in that city can be in any great degree due to its water supply, nor to its milk or food supply, nor even to defects in the city's house drainage, which is by no means exceptionally bad, but that some more widespread cause must be looked for. This cause he finds in the evaporation of bacillus-loaded water in the air in houses standing over dry and porous soils. In support of this argument he points out that whereas on the gravel soil in Dublin one person in every nine is attacked with typhoid, on the clay soil only one in one hundred and forty-five is attacked. These views are somewhat different from those usually prevalent as to typhoid etiology, but he is convinced from an extensive experience of typhoid in Dublin that there is a certain relation between its distribution and the geological character of the soil. This conviction is by no means necessarily in conflict with previous experience of typhoid as a water-borne disease; it is only on a par with the discoveries with regard to malarial fevers. As these fevers, although essentially air-borne, may by the absorption of their organisms become water-borne or mosquito-borne, so. by the evaporation from the soil of water containing typhoid organisms, typhoid may in a like manner come to be in a limited sense an air-borne disease. For the prevention of typhoid, as of all other diseases, the great desiderata are good and plentiful supplies of air and water—one is useless without the other. For real practical purposes we can draw no distinction between air-borne and water-borne disease. Indeed, all such carriers of infection may be looked upon as being in reality only proximate causes of disease. The immediate cause in most of the greater epidemics is to be found in the susceptibility of the individual. The microbes of typhus, of diphtheria, of influenza, and even of typhoid must be frequently present in a greater or less degree in the air we breathe and in the water we drink. Yet unless a certain pathological condition obtains in the human body by reason of which it becomes a suitable soil for the organism, it is very doubtful whether such microbes will grow and flourish. These pathological conditions, rendering the subject of them susceptible to infection, may no doubt be set up in the system by breathing foul air or drinking polluted water, and this preparation is a far more important factor in the production of epidemics than the actual number or conveyance of the organisms. The development of these organisms in the human body we may look upon as practically an artificial culture, for which a certain preparation is necessary; this preparation being an abnormal state of the system varying with reference to different forms of pathogenic life.—Dr. Foster Palmer, *Medical Magazine.*

A Bacteriological Study of the Blood in Acute Gastro-Enteritis.—G. Pieraccini and M. Nencioni briefly conclude a long and detailed description of clinical and laboratory experiments with the statements: I. That all the symptoms which accompany gastro-intestinal indigestion are a result of toxæmia of gastro-intestinal origin, but there is at no time any bacteriæmia. II. In a few grave cases alone, following deep lesions of the walls of the digestive tract, there may be a bacterial invasion of the whole organism.—*La Riforma Medica*, January 14–16, 1901.

The Possible Existence of a Reflux Passage of the Vesical Contents in the Ureters.—Filiberto Jacobelli, from the result of experimentation upon animals, concludes that the descending flow of urine constitutes the true protection of the ureters. When this is abolished, there is a rapid immigration of bacteria. Vesical stasis is not essential to this invasion, provided that there is cessation in the flow of urine in one ureter. Stasis has an indirect action, of course, but the ascent of the micro-organisms is not due to diffusion along a column of fluid, as Guyon holds, but to motion inherent in the bacteria themselves. This motion is opposed by the descending current. But should this be interfered with by a calculus, for instance, the ascent of the bacteria is thereby greatly facilitated. Possibly the origin of pyonephrosis from calculus may be accounted for in this way.—*La Riforma Medica*, January 4 and 5, 1901.

Health Reports.—The following cases of smallpox, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended February 16, 1901:

		Cases.	Deaths.
Smallpox—United States.			
California, Oakland	January 12th to 26th	4	
Florida, Jacksonville	February 2d to 9th	2	
Georgia, Jeffersonville	February 7th	2	
Illinois, Cairo	January 26th to February 9th	8	
Chicago	February 2d to 9th	2	
Pulaski Co.	February 2d to 9th	5

THE TREATMENT OF RHEUMATIC AND ALLIED DISEASES OF JOINTS COMPLICATED BY DEFORMITY.[1]

By VIRGIL P. GIBNEY, M.D.,
NEW YORK.

The impression one gets now and then in reviewing a desperate case that has yielded most happily to a line of treatment, prompts one to draw conclusions from inadequate data. If one attempts to tabulate or to review more in detail similar cases, the good impression is sometimes materially altered. The routine method of recording all cases coming under one's observation, good, bad, or indifferent, serves to check extravagant statements and to bring one nearer to terra firma. Personally, I know of no class of cases that serves better to bring about a conservatism in prognosis than the class which I purpose to discuss this evening. Quite sure am I that there are no more hideous deformities and no greater disability in any disease to which humanity is subjected than those generally included in the terms rheumatic and rheumatoid. I recall at this writing men, women, and children, all of whose motor functions are practically abolished, save that of respiration. The ossified man is not exclusively a freak in a museum.

Recently, while on a visit to an eastern city, I saw in a hospital a man, not yet thirty years of age, all of whose joints were ankylosed, from the temporo-maxillary to the digital, and in talking with the surgeon in charge, I learned that he considered this extensive ankylosis quite unnecessary. The question which I naturally asked without delay was, How can one prevent it? My profound respect for the skill of the surgeon led me to believe that if any one could give the desired information, he could. The reply was, in substance, by tonics, anti-rheumatics cautiously administered, protection of joints during exacerbations, active and passive movements combined with massage between the exacerbations. Records of my own cases lead me to believe that the treatment which he recommended will not always prevent the results which made this patient so helpless.

Before the presentation of the evidence gathered from my clinical notes, it would be well to define the terms in the title of the paper which forms the topic for discussion this evening. Rheumatic, when prefixed to a joint lesion, means an acute, subacute, or chronic condition, constitutional and characterized by certain deposits within the soft parts, articular or periarticular, impairing the functions of the joint in all degrees of disability. The constitutional features are blood changes as well as urinary, not at all times recognized by the pathologist, but nearly always appreciated by the clinician. A rheumatic joint is, therefore, one that is seldom non-articular, and presents changes in the contour as well as in the synovial sac, for instance in the roughening that is imparted to one's hand while the joint is moved, as if small rice bodies were rubbing one over the other; sometimes a tendinous crepitation, usually more marked in the joint immediately affected, but sufficiently pronounced in the corresponding joint.

Under the term "allied affections" may be included the bony ridges or fringes about a joint that occur in arthritis deformans — nodosis as it is sometimes called. The arthropathies dependent upon neuroses are included. I do not include the tabetic arthropathies, nor those of gout, although the line of distinction between rheumatism and gout is not always sufficiently defined to enable me to exclude gouty joints from the discussion, if the members of the society choose to contribute their experience.

Selecting from my office records patients whose later histories I have been able to obtain, I present for illustration and study some cases of multiple joint deformities; for example:

Case I.—Multiple arthritis deformans or osteo-arthritis; lesion first involved the knees, extending two or three months later to all the joints; great deformity with decubitus; unrelieved by any treatment. A lady, sixty-four years of age, seen in March, 1890, in consultation with Dr. Polk. She had been a cripple eighteen years, having been confined to bed for eight years of that period. When the disease began, it involved the knees, and she came under the care of one of the most accomplished orthopedic surgeons in this city. Although he was able to correct the deformity, the disease gradually extended to the shoulders, elbows, hips, and knees. She had taken on flesh, and there was no expectation when I saw her that anything could be done, except to relieve the decubitus, or by devising some appliance to relieve the pressure. The patient was not relieved by any treatment, and at the time of her death the ankylosis was as firm as ever. The details of treatment are not recorded, although the wealth and intelligence of the patient were such as to command the very best known to science, and it is presumed that nothing was left undone during the long course of her disability.

Case II.—Multiple arthritis deformans in an adolescent; deformity overcome by repeated operations; motion not restricted, but ability to walk on crutches; ten years later still able to get about, and disease apparently arrested. A lady, twenty-five years of age, was seen December 18, 1887. The first appearance of disease was when she was seventeen years of age. At this time galvanism was employed freely while the disease advanced. Her condition at the end of seven years was ability to walk only by slipping one foot after the other in a shuffling manner, the act accompanied by a noise distinctly audible, like bones knocking one against the other. The wrists were badly deformed, the fingers separated by deposits in the tendons, the ankylosis involving the shoulders, elbows, hips, and ankles. The only joints not implicated were those of the spinal column and the temporo-maxillary. I saw her again in 1891, two and one-half years later, when deformity was added to the ankylosis, and she was barely able to move with the aid of crutches. Six months later I made a careful examination of all the joints, put her under an anæsthetic in order to break up the adhesions, and put the joints in better

[1] Read before the Practitioners' Society, February 1, 1901.

position. I failed to move the right hip and right knee. The left hip was moved after the employment of much force and the deformity reduced about 25°. I succeeded in moving the left knee and brought it into a very good position—that of extension at 170°. Traction by weight and pulley, ice-bags, and morphine hypodermically, constituted the treatment immediately thereafter. A week later while she was under ether, I succeeded in completely reducing the deformity in the joints which had been moved at the time of the first operation. Plaster of Paris was applied at this time, and the pain was controlled by morphine. Two weeks later I succeeded in breaking down the adhesions at the right hip and right knee. Similar operations were repeated three or four times later, and passive movements were made in all the joints which had yielded. My last note was on May 25, 1892. The limbs were straight, the feet straight, and no adduction remained. She was actually walking with crutches. A letter under date of December 6, 1892, from the Home for Incurables, contained this paragraph: "I walk around considerably on my crutches. My knees do not bend, yet my hip is very much better." Dr. Jones told me, January 31, 1901, that she was still in the Home for Incurables, was not helpless, and went about on crutches; but the range of motion in her joints had not increased.

Case III.—Chronic rheumatic arthritis, following an acute attack, with endocarditis, joints involved those of wrists, hands, knees, and ankles; deformity so great that walking was impossible; walking restored, deformity reduced to minimum; treatment, hot air, hot fomentations, traction, brisement forcé, plaster of Paris, and apparatus. A lady, forty-five years of age, was seen by me May 18, 1896, and a diagnosis made of chronic rheumatic arthritis of both knees, hands, and wrists, with deformity. The disease began in the summer of 1890, six years prior to the date of my first observation, in an acute attack of articular rheumatism with an endocarditis as a complication. The acute soon gave way to a subacute process, and she was treated two months at Clifton Springs, and, in the fall of the same year, at Mount Clements, Mich. The first signs of improvement were observed in May, 1891, and it was not until September of that year that she was able to get out of bed. My records show her to have been, on May 18, 1896, quite helpless and stiff about the finger joints, with slight deformity of both

The range of motion was small at the wrist. held n[illegible]lders, elbows, and hips were normal, the knees articular[illegible] at 195°, painful, and there was much peri-

The trea[illegible]ltration.

[illegible]nt adopted at the hospital to which she was admitted [illegible]s traction on a double-inclined plane and iodide of [illegible]assium pushed to tolerance. In the course of five or [illegible]x weeks the limbs were sufficiently straight to justify [illegible]e use of a pair of long springs, in which she was able [illegible] stand. The apparatus was not tolerated well, and a[illegible]ut one month later the knees were encased in skin-[illegible]king plaster of Paris, the limit of extension being 16[illegible]. The plaster was removed three months later, and [illegible]assage was employed daily for four or five weeks. T[illegible] direct result of treatment seemed to be a diminutio[illegible] of infiltration and more motion in the joints. On N[illegible]vember 24, 1896, she was able to walk a few steps with [illegible]rutches, and she had a range of motion from 170° to 13[illegible]°. Early in December of the same year, the knees and hands were subjected to superheated air by the Tallerman-Sheffield process. After several treatments of this kind, it was noted that the fingers and thumbs could be moved a little more freely, but there was no decided gain in the knees. On December 15th I reduced the deformity in both knees under ether. The operation was followed almost immediately by massage, supplemented by hot fomentations, night and day. Two weeks later the operation was repeated, the deformity overcome, and the limbs were again encased in skin-fitting plaster of Paris. She left the hospital toward the latter part of January, 1897, and a report in May of that year showed that she was going about with a fair degree of comfort. The plaster had been replaced by the apparatus. On January 18, 1899, two years from the date of her discharge from the hospital, she was able to walk with very little assistance, to rise from a chair and stand alone, and even to go up and down stairs. Her limbs lacked a few degrees of being straight, and she was able to flex them to about 150°. She did not use the apparatus except for long walks. My last note was on October 19, 1900, when she was able to go about without the apparatus and with very little assistance from her crutches. There had been no recurrence of the deformity, and from being a helpless cripple she was able to help herself comparatively well.

Case IV.—Chronic rheumatic arthritis in an adolescent; fibrous ankylosis with great deformity, which was fully corrected under anæsthesia; relief a few weeks later; final results not obtainable. A boy, seventeen years of age, seen November 1, 1892, with lesions involving the hips, knees, and ankles, with great deformity and helplessness. I purposely omit the details of the deformities, merely stating that the hips, knees, and ankles were not only partially ankylosed, but greatly distorted. An attempt was made at this time to correct the deformity, with a fair measure of success. Plaster of Paris was employed, but soon removed on account of strain. Weight and pulley were employed until the second operation, about one month later. At this time the deformity was fully corrected, and plaster of Paris proved of great value in retaining the good position. He was taken home a fortnight later, and the last note I have of him is dated May 5, 1893, when the deformity had not recurred, but the helplessness persisted. I am unable to get a report at present writing.

Case V.—Multiple rheumatic arthritis in an adolescent; knee first involved when seven years of age; later, an acute attack of articular rheumatism, followed by exacerbations at long intervals; finally, bony ankylosis with deformity and marked joint effusion; ankylosis and deformity relieved by several operations; three or four years later, osteopathic treatment for one year, with improvement in locomotion; this was followed by relapse to disability; at present unable to walk. A boy, seventeen years of age, from Montana, seen October 17, 1893. His disease appeared to follow close upon a trauma when he was seven years of age, and a few weeks after the injury to his right knee, he developed a rheumatic fever, confining him to bed for a week only. He recovered, with shortening and disability of the right knee. Two or three years afterward an exacerbation occurred after another trauma, and it was a year later before the left hip and knee were affected. About two years later his ankles became involved. Six months prior to the date of my first observation, his neck and temporo-maxillary articulation became affected. In his history I learned that two maternal uncles and a maternal aunt had recurring attacks of rheumatism. The boy was able to walk on crutches, though he could not stand erect. His walking was practically on his axillæ, as he swung his hips and knees together when he moved. There was partial ankylosis of the left elbow and complete ankylosis of both hips, the angle of deformity being about 110° in flexion. Both knees were involved. The right was extensible to 150°, flexible to 99°, the left the same. Both were distended with fluid. A rheumatic grating could be felt in both knees on movement. The ankles were enlarged and the motion was limited to about one-half normal.

On two occasions, October 31 and November 6, 1893, passive motion was made under primary anæsthesia, but the deformity was not overcome. Traction on inclined plane, with local applications, including anodynes seemed to afford relief, so that he got about with a little more freedom. Under complete anæsthesia, January 26, 1894, the deformity in both hips and knees was overcome, great force being necessary to effect the reduction. Plaster of Paris was employed to retain the position. The discomfort caused by the plaster was so great that it was removed a few days afterward, and on the 9th of May, 1894, the operation was repeated. Plaster of Paris at this time was more comfortably worn, and a few days later, on removal, the hips and knees were found to be free from deformity. Massage for the next three months with hydrotherapy failed to accomplish any improvement, and, indeed, the deformity recurred to a slight extent. Toward the latter part of September the patient went home, and it was necessary to put him in plaster of Paris in order that he might travel with the minimum discomfort. Reports from time to time from that day to the present have not been encouraging, and the results on the whole may be set down as negative. Here is an interesting extract from a letter under date of January 28, 1901. "Finally I heard of Dr. A. T. Still and osteopathy, and decided to give it a trial. So I went down to Kirksville, Mo., and went under their treatment, and from the first treatment I began to improve, and at the end of a year I came home. The swelling was all out of my joints, and they did not hurt any more when handled. I was able to be out of doors all the time and go buggy riding and do the driving, and to be able to take a longer and rougher ride than the majority of well people. After I got home, an osteopath came and continued the treatment until about a year ago, when I was vaccinated. This settled in my joints. They got stiff, and I could hardly move, and I had to go to bed, and I have been in bed ever since."

My experience with the hot-air treatment in multiple arthritis with deformity has been disappointing. I could relate two or three notable instances in which this treatment has been employed most persistently and faithfully, with no better result than has been obtained by other methods as faithfully carried out. There is usually a temporary relief, but at later periods the cases are either *in statu quo* or, if anything, worse. In nearly every instance in which temporary relief has followed its use, relapses have been managed by the correction of the deformity under an anæsthetic and the prolonged use of plaster of Paris. Take as an illustration:

Case VI.—Chronic rheumatic arthritis of ten or twelve years' standing; for thirteen months totally unable to walk; hot air and massage persistently employed, with negative results; correction of deformity under anæsthesia, with retention in plaster of Paris; final relief to the point of walking with ease, and great helpfulness. A lady, twenty-eight years of age, whom I saw in consultation with Dr. Robert Watts, October 13, 1898. This lady had an attack of subacute rheumatism when sixteen years of age. There was some temporary deformity. Eighteen months before I first saw her, while she was in comparatively good health, her right elbow gave her some annoyance, and soon thereafter her knees became slightly flexed. Her hands became deformed, although there was a trace of this from her sixteenth year. For the last thirteen months she had been a cripple, totally unable to walk, had had hot-air treatment and massage, both for her knees and ankles. I found at my first examination that the knees were held in moderate flexion, and could not be extended beyond an angle of 150°. They could be flexed quite to 90°. The right elbow was moderately deformed and comparatively useful. The Achilles tendons were shortened on both sides, and there was some infiltration about both ankles. Tonics and massage had been employed, as well as hot air. Toward the latter part of October, 1898, I completely extended her legs and did my best to correct the deformity at the ankles under ether. Plaster of Paris which was applied immediately afterward remained on for two or three weeks, without removal, and there was a very fair range of motion. Extension was possible to 180°, though resisted. Massage and hot fomentations at night, with a posterior splint to retain the limbs in good position, completed the treatment. In order to encourage walking, jointed splints were employed, and toward the beginning of the year 1899 she was able to walk with little assistance. The knees were progressing to recovery. It was found, however, that the shortened tendines Achillis resisted, and the joints themselves were kept quite tender from this strain. I found it practicable to put the ankle which was the worse in plaster of Paris every two or three weeks, and, while the plaster was setting, to increase the dorso-flexion. All deformity of this foot was overcome within two or three months, and her walking became quite easy. During the past year I had occasion to treat the right ankle in the same way, and the result has been most gratifying. She requires no assistance in walking, can go up and down stairs, and leads a comparatively active life.

Another illustration of correcting deformity and retaining in plaster of Paris for a longer or shorter time is furnished by the following:

Case VII.—Chronic multiple rheumatoid arthritis, with deformity at hips and knees so great that walking was impossible; treatment, repeated operations with brisement forcé, followed by skin-fitting plaster of Paris for long periods; when the deformity was reduced to a minimum, hot air, massage, and traction; result, ability to walk with very little discomfort, and disease apparently arrested. A girl, seventeen years of age, was brought from the South, October 21, 1899. She suffered from chronic multiple arthritis, rheumatoid in character. The joints involved were the knees, elbows, hips, and the joints of the fingers. The limit of extension was 155° on one side, 110° on the other. The crepitation in the knees was very pronounced. Shortly after admission to the hospital, she was put under an anæsthetic and both hips and knees were extended to about 150° to 160°. It was difficult to go farther than this. Plaster of Paris was applied to retain, and on the removal of this, six or eight weeks later, traction on a double-inclined plane was employed. The joints were very sensitive, and required either hot or cold fomentations. On subsequent dates the deformity was further corrected. During the spring of 1900, hot air was employed for the wrist and knees daily for nearly two months. Progress was very slow, and skin-fitting plaster of Paris was resorted to with most marked relief. She was finally able to walk, and at the time of her discharge, July 31st, she was walking without any assistance, and presented very little, if any, deformity. The increase in motion at the hips, knees, and wrists was marked. A letter during the fall reported still further improvement. Full details of this case are not necessary; but she submitted frequently to anæsthesia and plaster of Paris, because after every operation the range of motion was notably increased and the disability so far relieved.

There are cases in which neuritis is a most distressing feature, and while immobilization after correction of the deformity affords relief from pain, there is usually very little gain in motion. My own experience leads me to resort to the minimum amount of violence, and brief periods of retention. A brief summary of the

history of a patient admitted to the hospital, July 10, 1893, will serve as an illustration.

Case VIII.—Multiple arthritis deformans, with recurring attacks of neuritis; disability very nearly complete; deformity corrected, but patient unable to use crutches, because of involvement of upper extremities; necessary to restore deformity so that a wheel chair could be used; sudden death three years after beginning of treatment, from cardiac disease. This was a woman, twenty years of age, who was pretty generally ankylosed, and the deformity of the lower extremities was such as to fit her to a chair. Trophic changes in the extremities were very pronounced. Operations were performed to straighten the limbs, but an old neuritis was rekindled, and the peri-articular lesions seemed to be increased. Subsequently I regretted that I had overcome the deformities, because she was unable to sit down, and the recumbent posture was necessary to afford any relief from the pain. Finally, abandoning all hope of motion, I flexed the knees and hips again, under an anæsthetic, so that she might occupy a chair. All treatment directed toward relief of the neuritis proved of little avail. A cardiac lesion beame most distressing, and she died quite suddenly in June, 1896.

Case IX.—Recurring attacks of peri-arthritis induced by trauma and complicated by neuroses; later chronic rheumatic arthritis with deformity and multiple neuritis; from almost complete disability and helplessness, restored to the use of her limbs; cure by no means complete. A lady, thirty-four years of age, from Georgia, was referred to me by Dr. Hunter P. Cooper, April 7, 1890. Transportation was exceedingly difficult and painful. Her temperament was highly neurotic, dating from girlhood. Her limbs and joints were excessively sensitive, tenderness extending in the course of the intercostal nerves as well. Her menstrual functions had always been regular and normal, and gynæcologists had pronounced her uterus and ovaries free from disease or deformity. The knees were held fixed at an angle of 90°, the calf and thigh muscles were atrophied. There were no bony enlargements about the joints, no effusion, no spinal tenderness or deformity. Her history is interesting, and presents six periods. 1. The left knee became stiff when she was ten years of age, after sitting for some time in school, and remained so for about one week. Muscular spasm of a neurotic nature seemed to be the cause. It was several weeks before the functions of the joint were fully restored. 2. Five years later, while jumping from a wagon, she had a sharp pain in the left knee, and the high flexors were soon in a state of tonic spasm. At this time there was a creeping sensation about the knee and a slipping, apparently of the tendon, such as is common in hysterical joints. This attack lasted a few weeks, but for years afterward she was troubled with her knee after long walks. 3. Seven years later, without any trauma as an exciting cause at this time, but while nursing a member of the family, and while under great mental anxiety, this same knee became involved as it had before, and swelling about the knee was added to the symptoms. It was fully ten months before she was entirely free from this attack. 4. Two years later, without any special cause, the left knee became again involved and was called a neurotic knee. This continued to trouble her until the next period of her illness. 5. This period was in the following year, when the right knee began for the first time to participate in the trouble. In the course of four or five months she got practically over the trouble in both knees. 6. During the following year, she had a sharp attack of pain in the right knee, which was so severe that she was obliged to go to bed, and she had not walked from that time to the date of my first examination, April 7, 1890.

I was unable to do anything without an anæsthetic, and it was found necessary to divide the flexors, after which, with considerable force, I was able to extend the limbs only to about 125°. The joints at the time of the operation were smooth, and the resistance was peri-articular. More or less neuritis followed the operation. It was fully three weeks before I was able to repeat it. After a half-hour of strong manual force, I was able to bring the right limb down to 180°, the left to 165.° Plaster of Paris was applied, and it was necessary to use opiates quite freely for the next two or three weeks. By dint of traction with weight and pulley, and hot fomentations, I was enabled during the next three or four months to bring the limbs perfectly straight, and to get her on her feet with the joints protected by apparatus. Treatment from this time forth was rather irregular, but was most obstinately resisted. In the summer of 1891, I employed brisement forcé under nitrous oxide. This was repeated from time to time until a small range of motion was secured. The last I saw of the patient was in May, 1892. She has been under treatment, largely by correspondence, from that time to about four or five years ago, since which time I have heard from her yearly, and the latest report is that she goes about the house and garden. She does not venture far from home, because of increased pain. She walks sometimes without the apparatus, sometimes with it, and has, I am assured, a fair range of motion.

Before passing from the subject of multiple lesions to individual joints, a reference may be made to this disease as it occurs in children. We have at present employed in the sewing-room of the hospital a young woman, admitted as a patient in December, 1886.

Case X.—Multiple chronic rheumatic arthritis in a child; for many years confined to a wheel-chair, and now so far relieved that she goes about without crutches or braces; is an employee in the sewing-room of the hospital. When she was seven or eight years of age, she remained for two or three years under treatment, tonic, protective, etc., with gradual improvement. For many years now, she has been able to get about with very little discomfort, but the joints of the lower extremities, as well as those of the upper, are more or less impaired as to motion. The results in children are no better than in adults. The treatment of individual joints is followed by better results than when multiple lesions exist.

The rigid spine has been discussed so much by neurologists within the past two or three years under the name of spondylose rhizomélique, that a further presentation of the subject would be superfluous. The clinical features and the pathology of rigid spines have rather overshadowed the treatment. Among my records, I find a number of cases in all stages of the deformity. In the majority I have not obtained any satisfactory results by any methods yet suggested. The treatment which has been most efficient has been immobilization of the column by plaster of Paris or steel braces, and by active counter-irritation, preferably with the Paquelin cautery.

Case XI.—Spondylitis with rigidity; rheumatic element with neuritis complicating; relieved by Paquelin cautery and apparatus. A gentleman, fifty-two years of age, from Springfield, Mass., was referred to me, November 15, 1890, by the late Dr. Loomis. The patient's spinal rigidity arose from exposure to cold, in December, 1889. He had, at the time of my first examination, a good deal of neuralgia, a stooping gait, and a step like one with Pott's disease. There were decided thickening over the spinous processes of the upper dorsal vertebræ, and much tenderness on pressure. I fitted him with a spinal brace, and used the Paquelin cautery quite freely. At the end of three or four

months, he was walking quite erect, and he was so impressed with the relief he got from the use of the cautery, that he purchased one himself, and had his wife make the applications. At the end of a year, he passed from observation, but in October, 1893, I had an opportunity of examining him and found him perfectly well, without deformity, free from rigidity, and I am sure that he has remained well to the present time.

When the lesion involves the shoulder, it is usually peri-articular, and passive motion under an anæsthetic is as a rule attended with excellent results. I could place on record a number of cases which would bear me out in the above statement, but I hesitate on account of the limited time at my disposal. Before mentioning the shoulder joint, I should have spoken of the temporo-maxillary ankylosis, and the treatment which has proved efficient.

Case XII.—Chronic multiple rheumatic arthritis with temporo-maxillary ankylosis; relieved by resection. About two years ago, we had at the hospital a boy who was suffering from multiple lesions of this kind, and for at least a year, while we were attending to his other joints, and getting him in condition for walking, all efforts at relief of the maxillary joint failed. For weeks at a time we would have his mouth held open by wedges in his teeth, but whenever the wedges were removed, ankylosis would recur. He fed himself in a space where one or two teeth had been removed. I determined finally upon a resection of the articular end of the inferior maxilla, had Dr. Weir see the case, and he very kindly operated at the hospital, with most gratifying results. I think he has already placed the case on record.

The elbow is a joint which ought to be relieved by brisement forcé, but this operation must be often repeated and every procedure of this kind followed by pretty vigorous massage, and active and passive movements. The following will bear me out in the above statement:

Case XIII.—Fibrous ankylosis of elbow in awkward position, following an attack of rheumatism; cured by many operations of brisement forcé under anæsthesia; massage always followed the operations. A lady, twenty years of age, came under my care November 16, 1897. Her father first consulted me about her in August, and at this time she was under treatment in a private hospital in London, without any noticeable relief. I could learn really very little of her history, but when I first saw her she had a range of motion at the elbow from 115° to 110°. The infiltration had subsided, but the radio-ulnar articulation was involved as well as the radio-humeral. I subjected the elbow to hot air for nearly one month, having pretty vigorous massage employed after each treatment. Very little headway was made, and on December 16th I began moving the elbow under nitrous oxide, and continued this every three or four weeks until March 1, 1898. It was remarkable how many adhesions were broken up on every occasion. The range of motion increased from that time without interruption. I saw her on January 8, 1899, and the range of motion was perfect—flexion, extension, pronation, and supination.

I was not so fortunate in two other cases, the details of which I purposely omit; but I did succeed in giving more usefulness to the extremity by reason of the better position. In one of these I employed hot air for a long while, without appreciable results.

Case XIV.—Ankylosis of elbow after rheumatism; no motion established after repeated operation, hot air and massage. Within the past few days I have had a letter from the lady, who assures me that she can use the forearm and hand for all practical purposes, although there is no motion at the joint.

The other, Case XV., was treated by forced movement under gas on four occasions, and the result, after the last, promised well. This was in 1891. A day or two ago I had a letter from the gentleman, saying that there was no motion, but the position was good, and he had fair use of the extremity. I believe when this treatment fails, a resection of the joint would be good practice, although I have no experience to record.

Case XVI.—Ankylosis of wrist after rheumatism; marked relief after brisement forcé, supplemented by traction splint; ultimate result reported as a cure. The wrist joint offers, by reason of the expansive articular surface, still greater obstacles, and the only case I have to record is in a lady twenty-five years of age, who submitted to the operation two or three times with a little gain. My last observation was on February 6, 1891, one month after the beginning of treatment, when I was able to record a small range of motion. I provided her with a traction splint with a movable joint, and urged a continuance of active and passive movements. A letter under date of July 10, 1892, nearly eight months later, brought a complaint that the wrist was weak, and that she had been disappointed. It is only fair to state, however, that this was in reply to a demand for the settlement of her account. A mutual friend saw her in 1896, at a watering-place, and found her quite enthusiastic about the cure of her wrist. My friend saw her move it in flexion and extension, and was assured that it was cured.

An ankylosed hip from rheumatism or osteo-arthritis responds poorly to any form of treatment, although I have a few cases, which speak well for repeated movements under an anæsthetic.

Case XVII.—Chronic rheumatic arthritis of hip with fibrous ankylosis; brisement forcé on several occasions; result, at present, good. I have now under treatment a lady from Rochester, whose hip last fall was firmly ankylosed at an angle of about 135°. At the time of the first operation, an enormous amount of force was required to break up the adhesions, and the noise was so loud that the nurse and assistants were sure that I had fractured the femoral neck. I dissented most decidedly, and was able to demonstrate the opinion I held. There was, however, a marked crepitation in the joint, which was not present at subsequent operations. The protection was continued for two or three days after the operation, and then active and passive movements were employed. Altogether she has had six or eight forcible movements of the joint under anæsthesia, and the range of motion extends over about 90°. This case differs markedly from one treated in 1891.

Case XVIII.—Chronic rheumatic arthritis of hip; partially relieved by a traction splint; subsequent involvement of all joints, and all treatment attended with negative results. A man, forty-seven years of age, referred to me by Dr. Cook, of Hartford. An arthritis of the right hip followed an injury eight years previously, and he apparently got well. Four years later an exacerbation ended in decided stiffness of the joint. There was a small range of motion, say from 150° to 135°. There was no signs of abscess, and I had very little difficulty in making out a case of chronic rheumatic arthritis. I advised a hip splint by day and weight and pulley by night. Six months later some progress was reported, and I heard nothing further of the case until January 30th of the present year, when Dr. Cook, in reply to a letter, wrote that the patient had recovered with a stiff hip, perfectly painless and useful. Subsequently the disease attacked nearly every joint in his body, and Dr. Cook was unable to do anything for his relief. The patient died about three months ago, but up to that time the hip had remained *in statu quo*.

Whatever enthusiasm has come to me in the management of joints thus afflicted, has come by reason of some extraordinarily good results when the knee was

involved. I must place on record a few of these, and beg to present the case of Miss P——:

Case XIX.—Chronic rheumatic arthritis involving both knees, of many years' standing; deformity and disability; cure at the end of three years; in seven years no relapse, cure perfect. She was about fifty years of age when she came under my care, August 4, 1891. Her history was this: Twenty years ago, while stepping out of her carriage, she strained her right knee. Three months later there was fluid in both joints, and she was treated with splints in bed for three or four months. For the next twelve or fourteen years she was always careful of the knees, although using them in moderation. Then she turned her knee rather sharply and suffered for several weeks. Ten months later she had another strain, and then began to use crutches, which she used at the time I first saw her. She was quite helpless, and one knee was more involved than the other. There were general infiltration, resistance to all movements, crepitation, etc. The right ankle was slightly involved. Treatment was advised, but postponed until April 15, 1893. I put her on a double-inclined plane, used hot fomentations and the Paquelin cautery, and administered iodide of potassium. After getting the limb straight, I applied plaster of Paris, skin-fitting, which was worn for four or five weeks. This was followed by an apparatus. Improvement went on without interruption. An occasional use of the cautery from this time to August 3, 1894, was all the treatment she had. In October and December of that year, I found the range of motion practically normal. In 1896 there was no impairment of function whatever. As a city missionary, she was using the limbs climbing up and down stairs of tenements, without pain or discomfort. With the exception of a strain, in February, 1897, there has been no recurrence of any symptoms. From that time to the present I have seen her occasionally, and she still remains perfectly well, and walks and travels without any discomfort. The treatment in her case was, therefore, protection to the joint, gradual correction of the deformity, and the internal administration of potassium iodide.

Case XX.—Chronic rheumatic arthritis of knee, assimilating a sarcoma; most marked relief obtained by the prolonged use of plaster of Paris, infrequently repeated; cure completed by a jointed splint; result perfect. A lady, thirty-eight years of age, was seen at Governor's Island, April 7, 1894, with a diagnosis of rheumatic arthritis of the right knee with some involvement of the left. Her lameness was of eight months' duration. When I saw her she was quite helpless, the right knee much enlarged, and the contour completely effaced. A protective apparatus was employed, but little relief was afforded until October 14, 1894, when I began the use of plaster of Paris and crutches. I made it a point to fit the plaster very closely, and leave it on for six or eight weeks at a time. This was continued for nearly a year, and improvement was marked whenever a new cast was applied. After all infiltration had subsided, there was a fair range of motion, and a brace, extending from the thigh to the shoe, allowing limited range of motion at the knee, was adjusted, and there was little further of interest to be noted in the case. By the spring of 1896 she was well. There was a range of motion from 180° to 90°, an easy gait, and up to last reports, two or three years ago, there was no recurrence.

I have notes of a number of cases treated similarly, but with less persistence, in which the results have not been so satisfactory. One of the most obstinate was that of a man twenty-eight years of age, whom I saw on March 21, 1899.

Case XXI.—Ankylosis of left knee after acute rheumatism; three months' daily use of hot air with negative results; repeated operations of brisement forcé; later, plaster of Paris; final result, small range of motion, no deformity, with ability to walk long distances without support. There was deformity and almost complete ankylosis of the left knee, left over from an attack of acute articular rheumatism in March, 1898. In August of that year, the superheated-air treatment began in Philadelphia, and for three months daily he was subjected to a temperature of 340°. An accident occurred at the end of this period, and his leg was badly burned. When I first saw him, the angle of greatest extension was 140°, of flexion 130°, 10° possible of motion. I moved his knee under an anæsthetic on various occasions, at one time followed by plaster of Paris, and at another by active and passive movements, and, after a long time, I rather despaired of accomplishing good results. In August, 1899, after nearly six months' continuous treatment, there was little if any motion, but the limb was straight. Treatment was resumed in November, 1899, and continued to February, 1900, with at least a dozen operations. In January, 1900, Dr. Janeway saw him with me in consultation, and doubted whether the patient would ever get any motion. I saw him on the 2d of July, and he could extend the leg to 175°, and flex to 150°. The patella moved easily from side to side. He was walking freely and with very little discomfort. I have not traced the case for a late result, and hence am unprepared to state his condition at the present time.

Case XXII.—Ankylosis and deformity of knee, following confinement; later, a rheumatic attack with cardiac complications; deformity and pain about the knee accentuated; failure to get relief after treatment at Hot Springs, operations under anæsthesia, apparatus, and osteopathy. A lady, thirty-one years of age, referred to me by Dr. E. G. Janeway, March, 1896. Twenty months prior to this date, and about two weeks after confinement, she had pain in the left foot, with a little swelling. Two or three months later, she had an attack of rheumatism involving the ring finger of the left hand, arm, shoulder, and knee. There was much neuritis in this attack. She recovered at the end of three months in all the joints, except that of the knee. At the hot springs of Virginia the deformity of the knee yielded a little to the bath treatment. When I first saw her, the knee was fixed at an angle of 120°. The acute symptoms were so pronounced at this time that I employed hot fomentations, with traction in bed on a double-inclined plane. At the end of a month I succeeded in breaking up the adhesions about the knee, under nitrous oxide, and extended the knee to 160°. Massage was at once employed, while traction was continued. The pain following this operation was most excruciating, and lasted a week or ten days. At the end of a month, the limb could be extended to 180°, and flexed to about 155°. It was three months before I saw her again, and then the angle of greatest extension was 160°. Further operations were declined, and treatment was largely expectant. Six months afterward, a vigorous osteopathist undertook treatment with negative results. At last accounts, February, 1899, there was very little pain, but there was very little gain in the range of motion.

I had intended to place on record a number of cases in which the neurotic element was a distressing feature, and in which the treatment was necessarily prolonged, but they all read alike. In nearly all, the deformity has been overcome, and a small range of motion has been established, and the patients have been restored to a degree of helpfulness that finds expression in lasting gratitude.

I am tempted to dwell a little on the results obtained in cases in which the disease involves the tibio-tarsal and mid-tarsal joints. Suffice it to say, how-

ever, that the majority of my patients have been relieved, adhesions have been broken up, a useful range of motion has been established, and the lesion itself has proved less intractable than in some of the other joints.

I am free to confess, in concluding this paper, that it is difficult to fix upon any one form of treatment that has yielded the best result, but I cannot refrain from commending the forcible breaking up of adhesions when inflammatory conditions have subsided, a frequent recurrence to these operations, and the discriminate use of plaster of Paris. My belief in the efficacy of absolute immobilization as a promotion of absorption of chronic inflammatory products grows stronger year by year. The protection of joints with a limited range of motion, by apparatus within the bounds of this motion, is also to be commended. There is scarcely any joint in the body but that will tolerate a great amount of force at certain times. Only recently have I attempted the correction of a deformity in a rigid spine, by extension with moderate force, and the result at the present writing is gratifying, to say the least. The apparatus employed is that used in the correction of the boss of the deformity in Pott's disease, and is employed without an anæsthetic. In a few instances I have recommended an anæsthetic.

To sum up in a word the treatment which has been most efficient, I would say, a judicious management of the case throughout, correction of the deformity, partial restoration of function which renders the patient helpful; and improvement is sure to follow.

AN IMPROVED METHOD OF EXAMINING THE FEMALE BLADDER, ADMITTING INTRAVESICAL OPERATIONS AND TREATMENT OF THE URETERS.[1]

By WILLIAM R. PRYOR, M.D.,
NEW YORK.

It will not be necessary for me to detail the various methods of cystoscopy, nor to enter into a criticism of all of them. You are contemporary with their evolution, and are fully aware of the technique of the several procedures. After showing you these instruments for illuminating the bladder, for removing foreign bodies, and for catheterizing the ureters, I will make a demonstration on this cadaver. But a few words on the principles involved in the procedure may not be amiss.

Instruments.—As dilators I employ the straight male sound, from 25 F.–36 F. The cystoscope consists of a main tube for inspection, alongside of which is attached a smaller tube for carrying the lamp and the stem which holds it. The tube for illumination extends beyond the tube for inspection, and consequently the rays of light project beyond and outside the tube for inspection, no rays entering the latter. The light illuminates 100° of the bladder circumference, 260° being in shadow. The heat from the light is taken up by the metal of the tube. The lamp, lamp-holder, and wires are completely insulated. Neither urine nor other fluids can short-circuit the current when this apparatus is connected. The tube for inspection is perfectly free from rays of light as well as from the lamp, and therefore inspection is made of an illuminated object and not through rays of light (Fig. 1). The tube is also free for the purpose of making applications and passing the ureteral catheters, removing neoplasms and foreign bodies. The tubes measure: 0.6 cm. x 1 cm., 1 cm. x 1.3 cm., 1.2 cm. x 1.5 cm. Each tube is 8.7 cm. in length, exclusive of the obturator. I have had a tube made 11.5 cm. long, for use in bladders which are drawn high up by pregnancy and tumors. The smallest size is for use under cocaine. I usually employ size 2 when the patient is under narcosis. The battery is dry and the conducting wires are insulated in a rubber-covered cord. The tubes and obturators are sterilized by boiling, the lamp by wiping with five-per-cent. carbolic-acid solution.

The great advantages obtained by this cystoscope are: a tube for inspection free from obstructions and free from light rays, either direct or reflected; the

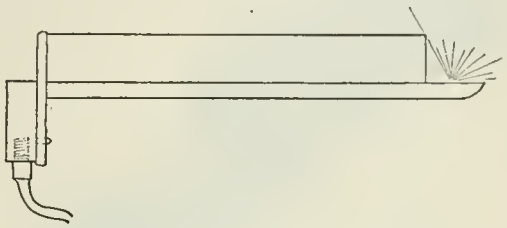

Fig. 1.—The Cystoscope. The obturator is not shown.

absence of necessity for focussing rays of light, which embarrasses the operator in his manœuvres when a head mirror or lamp is employed; the passage of the rays of light directly to the object to be inspected; the absence of all the disadvantages inherent in the use of the cystoscope of Nitze; and, lastly, the perfect ease with which demonstrations can be made; absence of heat; absence of urine about the trigone; absence of the necessity for pumping out urine.

Posture of the Patient.—This plays a very important part in the examination of the female bladder. All of you who have seen a case of exstrophy of the bladder know the degree of the intra-abdominal force upon the bladder. When the bladder is empty this force usually presses the bladder into a triangular

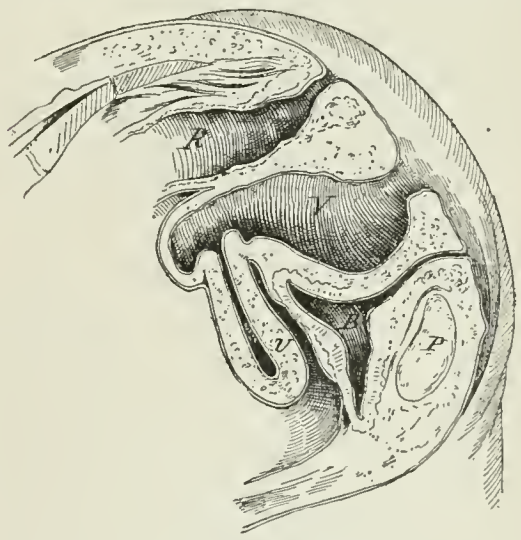

Fig. 2.—The Position of the Organs in the Knee-Chest Posture. (Frozen section by Berry Hart.)

form. When the viscus is thus shaped it is impossible to make a proper cystoscopic examination of its interior. The reason for this is found in the folds which the mucous membrane assumes when the bladder is empty. Therefore, it is very desirable to distend the bladder so as to straighten out the rugæ and make a plane surface of its interior. This is done by either fluids or air. Of the first I need speak no further than to ask you to consider that first simple proposition of your elementary physics which deals with the passage of light rays from a light medium, the air, to a denser, water. Thus, direct inspection through an open speculum of a water-filled bladder is impracticable; and when fluids are employed some form of

[1] Read before the New York County Medical Association, January 21, 1901.

closed tube must be used, with the attendant difficulties of treating the bladder when diseased conditions

Fig. 3.

are found, of catheterizing the ureters, and of removing neoplasms and foreign bodies. We are, therefore, compelled to employ some method which will distend the bladder with air and secure an unobstructed view of the entire bladder wall.

When Kelly first brought out his method it marked a distinct advance. Upon first seeing him employ this I was struck with the embarrassment caused by the constant presence of urine, and by the inadequate distention of the bladder. Furthermore, the light by which the organ was illuminated was a reflected light. The first position he used was the dorsal with elevated hips, but no release of intra-abdominal pressure was secured. I saw this at once and devised in February, 1894, my table which secured the proper posture. This I have used ever since. Kelly changed the posture of his patients to the knee-chest, the one he now employs and the one I wish to contrast with mine (Fig. 2).

"In virgins and nulliparæ the bladder walls balloon out so much upon atmospheric distention that the base is carried up toward the sacrum, and becomes so markedly concave that the ureteral openings can scarcely be seen; the observer has to drop the handle of the speculum to such an extent that he is obliged almost to bring his head under the pelvis to find them. This difficulty will be obviated by first introducing into the vagina a little speculum which lets in the air and causes the anterior vaginal wall to drop down, bringing the base of the bladder into the plane of vision. If the distention is still too great after this manœuvre, the difficulty may then be overcome by introducing within the vagina a cotton pack large enough to hold the anterior wall down, or a small inflatable rubber bag, or an instrument shaped like a spatula with a strongly curved handle to make pressure on the vaginal wall and bring the ureteral orifice into view."

I quote Dr. Kelly's words, for he can express these disadvantages of the knee-chest posture better than I. But even when the embarrassing recession of the ureters has been overcome by distention of the vagina, the element of focussed light is present. All the disadvantages of the three methods of examining the bladder which I have mentioned are done away with by the procedure I offer you.

The patient is put on the back in the lithotomy posture (Fig. 3). With straight sounds I dilate the urethra to a 30 or 36 F. But no dilatation is needed when the smaller tube is used under cocaine. I then introduce the obturated speculum and evacuate the urine.

In women who have flaccid abdominal walls or who have marked prolapse of the anterior vaginal wall it is advisable to pass the catheter immediately before they are placed on the table; for after such are on the table in the lithotomy posture the bladder is not easily emptied. The bladder having been emptied, the table is lowered into the requisite angle, usually about 45°. The uterus now sinks away from the pubes and drags with it that portion of the bladder which is covered by peritoneum (Fig. 4). This, being attached also to the pubes, is straightened out. At the same time the cervix sinks away from the vulva and the base of the bladder is also straightened. The bladder assumes the shape of an open equilateral triangle with rounded corners. The extent to which this gravitation of the pelvic viscera takes place is readily seen by inspecting the suprapubic area. This will be found much sunken. The advantage of this posture over the knee-chest is due chiefly to the straight lines which the vaginal segment (in which the ureteral orifices are found) and the pubic segment assume.

In the knee-chest posture the bladder can be made to dilate somewhat by air, but both the pubic and vaginal segments are thrown into curved lines. In the knee-chest posture the bowel and vagina being closed, as the air rushes into the bladder the pubic segment actually falls further anterior than normal, while release of the intra-abdominal pressure from the anterior plane of the pelvis acts just as would a

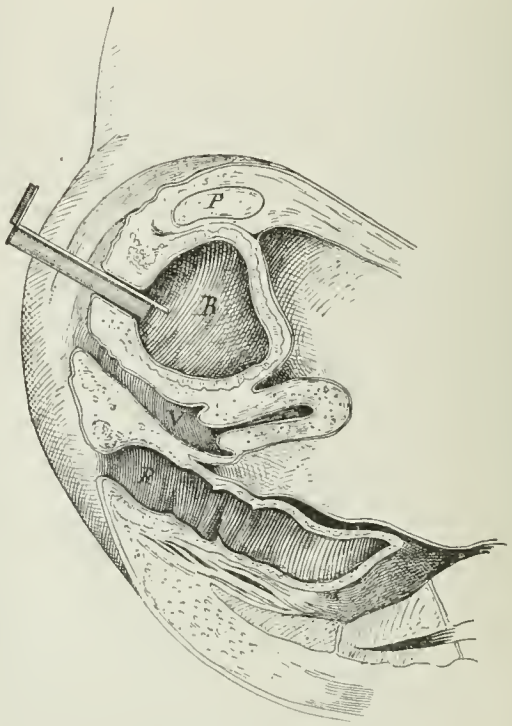

Fig. 4.—Shows the Effect of Atmospheric Pressure on the Bladder in my Posture. (Pryor.)

bladder overdistended by urine; the cervix falls backward, and the vaginal segment of the bladder approaches the sacrum and rectum, thus concealing the ureters.

Gravity in the knee-chest posture militates against

a symmetrical dilatation of the bladder. If you open the vagina at the same time you do the bladder, as is often necessary before you can see the ureters, of course the posterior pelvic plane moves up and the difficulty is partially overcome.

When you place a patient in the knee-chest posture and open the vagina, the posterior vaginal wall recedes toward the sacrum (Fig. 2). Leave the vagina closed, but allow atmospheric pressure to act on the interior of the bladder, and the vaginal walls are practically one. Thus the anterior vaginal wall recedes toward the sacrum with the posterior, and the ureters are dragged out of easy access and view. With my position no such thing occurs, for the uterus, tending by gravity toward the pelvic brim, becomes partly an abdominal organ and symmetrically opens the bladder as air is admitted to the latter. You can experimentally defeat this by holding the uterus in the pelvis with the closed fist on the belly before lowering the table; and you can overcome the obstruction to the descent of the uterus, in fat women, by lifting up the belly fat after the table is lowered.

There should be no restraint by clothing or dressings as the table is lowered.

Inspection.—I first examine the ureteral orifices and the trigonum, for there we find most of the lesions. I then sweep the instrument over the lateral vesical walls, and by turning the handle down make the light illuminate the pubic segment. I know of no other method by which every portion of the bladder wall can be inspected. Since I have begun employing this method I have found lesions above the trigonum sufficiently often to convince me that no search of the bladder should be considered thorough which does not embrace all its cavity. In catheterizing the ureters for the purpose of securing separate specimens in ureteral and kidney lesions, I have been able to secure sterile urine from both ureters even when acute cystitis existed (bacillus pyogenes). This will show with what ease the ureteral orifices can be cleansed and the ureteral catheters passed without touching the sides of the cannula. My cases I will not detail, as they will not aid in my explanation of the physics of the questions I introduce. As a method of demonstration to students it is most excellent. I have shown both ureters to sixty men and passed the ureteral catheters within an hour.

A question of priority is always raised when a presumably new method or instrument is shown. My table and posture I devised in 1894. I bought Chetwood's urethroscope in November, 1899, and at once saw its defects as applied to the female bladder. I gave an instrument maker my order with a written detailed statement of what I wished, and received the first week in December, 1899, my perfected instrument. I made demonstrations with it to my classes and showed them the ureteral orifices and bladder mucosa during December, 1899.

The idea of a separate tube for the light alongside the tube for inspection is borrowed from an old cystoscope which employed this arrangement for the purpose of sucking out the urine while reflected light was thrown in. Otherwise in every way the instrument is original as is the posture.

Lymphadenia.—There is no specific. Regular life, avoidance of constipation, open-air exercise are indicated. Iodine if given at all should be in the form of iodide of iron. No importance is to be attached to the injection of red bone marrow. Arsenic may be combined with small doses of opium, or arsenical water, such as La Bourboule, may be given for a long time.—LEMOINE.

SOME FACTS REGARDING "UREINE."[1]

BY A. F. CHACE, B.S., A.B.,
AND
WILLIAM J. GIES, PH.D.,
NEW YORK.

WE were amazed, recently, on reading Dr. William Ovid Moor's account of "The Discovery of Ureine, the Principal Organic Constitutent of Urine, and the True Cause of Uræmia,"[2] to find that such sweeping generalities had been based upon methods so defective chemically. Our faith in the older observations that urea is the chief organic constituent of urine has been so complete, and our confidence in the deductions of far-reaching significance based thereon has been so thorough, that it was impossible, in the absence of real chemical evidence in favor of Dr. Moor's assertions, to accept his inferences that "the human urine contains a liquid [!] organic body, in a quantity superior to urea," and that "this organic liquid (ureine) is the most characteristic component part of urine."

Dr. Moor began his paper with the statement that he found the human urine to contain "a large quantity of some organic substance which gives in a very intense manner" the same characteristic blue reaction with a solution of ferricyanide of potassium and ferric chloride that may be observed when morphine and various alkaloids are treated with a solution of these two salts of iron. "Numerous and exact investigations," he adds, "forced him to the conclusion that none of the known organic or inorganic components of urine could account for this intense blue reaction, and that, therefore, some chemical body, until the present unknown, must be the cause of this strange phenomenon." We do not know, of course, how "large" the quantity of this substance was, nor how "intense" the reaction it caused; but the fact that Gautier,[3] Bouchard,[4] Aducco,[5] and others have found basic bodies in both normal and abnormal urine giving this reaction, makes it seem probable that Dr. Moor's "strange phenomenon" is to be referred, in part at least, to substances of similar character dissolved in urine, and not especially to anything unknown, as he has assumed. There is sufficient reason to believe that each of these observers was dealing with chemically pure, individual substances, and that these products were not contaminated with ureine.

Dr. Moor goes on to say: "It is not surprising that the existence of a metabolism product of such great importance should, until the present, have escaped our knowledge, for every urinary analysis has been made with the firmly rooted idea that urine is a liquid composed of water and of inorganic solid ingredients"! In the light of every-day knowledge regarding the quantity of such organic substances as urea, uric acid, creatinin, hippuric acid, etc., in normal urine and their relation to metabolism, this inaccurate statement is worth considering only because it suggests how much of fact there is in the ureine story.

In one place Dr. Moor concludes that "this organic metabolism product of the human body (ureine) belongs to the group of alcohols of the aromatic series; at a temperature of about 80° C. it begins to split into

several bodies belonging to the class of aromatic oxy-acids." At another, he states "ureine is a ferment, which has a potential energy of at least 130° C." Yet neither of these conclusions is accompanied by any statement of fact upon which to base them, and only imagination seems to account for them. Thus, ureine is said, in this connection, to be "the principal [!] cause of the ammoniacal fermentation of urine, as without its presence urea cannot be decomposed into ammonia and carbon dioxide." Again, "only a temperature of above 130° C., perhaps 140° C., can split urea into ammonia and carbon dioxide." All this in mere dogmatic statement, with no experimental justification and entirely in opposition to the numerous results of very laborious work for years by many careful investigators.

Dr. Moor also says: "Urea, in many respects, is just as indestructible [does he mean undecomposable?] as iron, silver, or any other elements, for the strongest mineral acids do not decompose [!] it, but simply combine with it." Is it not true that one of the properties of all matter is "indestructibility"? Dr. Moor, however, may have intended to use the word in a different sense from that customarily applied to it. If he means to refer to comparative stability, what of the fact that even dilute hydrochloric acid decomposes urea? Everybody knows, also, how quickly urea is broken up when concentrated nitrous acid, for example, acts upon it.

In all of the unaccountable assumption characterizing Dr. Moor's paper, there is nothing, however, to compare with the biological burlesque at the close. "Without ureine," he says, "all organic matter would become converted into urea, which would remain in nature without any use, and thus within a limited period of time all vegetation and animal as well as human life would cease."

Truly, as Dr. Moor remarks, "this wonderful organic fluid," this "mysterious chemical body," ought to receive very careful study. We ourselves have been of the opinion, however, that the method by which it has been made deserves much more attention.

With a view of testing these points experimentally, we have lately made several preparations of ureine, not only by the method given in the paper alluded to at the outset, but also by the improved process outlined in Dr. Moor's latest communication.[1]

Reviewing the method, as improved, the normal human urine, varying in quantity from 1.5 to 49 litres, was evaporated at a temperature not above 50° C., usually at 48° C., until no more vapor could be seen arising from the surface of the fluid, even after the application of Dr. Moor's "indispensable" and "delicate test"; as long as rapid withdrawal of the thermometer from the fluid, following directions, caused "a puff of vapor ascending from the mercury bulb," the evaporation was continued. It stands to reason, of course, that even though no steam can be seen arising from the evaporating fluid under these conditions, insensible vapor may continue to form at this point, and a large proportion of water may be left in the fluid. Certainly, water cannot be completely removed from a urinary residue at such a low temperature—a matter of importance, bearing not only on the separation of urea, etc., farther on, but also influencing the percentage of ureine.

The concentrated fluid, still containing a fairly large proportion of water, of course, was next kept in an ordinary freezing mixture, at 10° below 0° C. for several hours. (Dr. Moor says: "We reduce the temperature of the liquid, if possible, to 0° C." The length of time the mixture is to be held there is not given.) A heavy precipitate, mostly of inorganic matter, quickly separated. Absolute alcohol at 10° below 0° C., equal to half the quantity of fluid, was then added to "facilitate filtration," and this mixture filtered in small quantities (while below the freezing-point), thus removing most, though by no means all, of the urinary salts.

The main bulk of urea was thrown out of this filtrate in the form of urea oxalate with powdered oxalic acid (1 gm. for each 100 c.c. of urine used), and then alcoholic solution of oxalic acid—thirty-per-cent solution—was added "until no further precipitate was formed." By very careful work at this point we found that immediately visible precipitation could not be relied upon as a true indicator of complete separation. Consequently, in order to avoid excess of oxalic acid (Dr. Moor says nothing about this) its alcoholic solution was added in small quantities at intervals of several hours until the filtrate gave only a delicate reaction for oxalic acid, with calcium chloride in the presence of acetic acid. At this stage only a slight permanent precipitate formed on adding a little more alcoholic solution of oxalic acid, even after standing over night. It must not be forgotten in this connection, however, that urea oxalate is somewhat soluble even in absolute alcohol. But under these conditions, with considerable water left in the previously evaporated residue, the alcoholic mixture possessed increased solvent action. In testing with calcium chloride, the positive reaction just referred to was doubtless due in part to the combined oxalic acid in solution in the form of urea oxalate. This method, even at best, therefore, certainly does not suffice, as Dr. Moor seems to assume, for complete and satisfactory removal of urea.

The filtrate from the urea oxalate was next concentrated at 48° C. In a few hours a thick, dark-brown, oily fluid was obtained. This Dr. Moor has the assurance to speak of as a chemical individual—"ureine"—admixed merely with pigment and "some saline matter." He says that at this point "there is nothing but ureine, together with coloring matters." He adds that this ureine "is sufficiently pure to satisfy all exigencies of clinical medicine and of physiology," and then, inconsistently and with little reason, concludes, "for it is evident that the presence of some saline matter cannot influence the qualities of ureine." How, we may ask, were the other organic substances of the urine having physiological influence removed, such as indican, aromatic oxy-acids, toxic basic bodies, etc., etc.? Further, what reason is there for believing that the presence of urinary saline matters cannot influence the toxicological qualities of ureine—potassium salts for example?

In the preparation of chemically pure (?) ureine from this point, following Dr. Moor's recommendations for making ureine for merely chemical purposes, the alcoholic solution was "treated successively with barytes to remove the sulphates and phosphates, with nitrate of silver to separate the chloride of sodium"! This addition was made very carefully in each case, to avoid excess of silver and barium, a precaution not referred to by Dr. Moor. But did all of this result in removal of inorganic salts contained in the urinary residue, or did it effect mainly their transformation? We think we are safe in saying that the potassium chloride, for example, still present in ureine was merely converted into soluble nitrate of potassium and into insoluble chloride of silver. The latter was filtered off later, but the nitrate remained in the ureine, possessing even more toxic influence than the corresponding chloride. In short, these reagents, speaking generally, removed radicles, not salts; the amount of inorganic matter left behind was undiminished, if not increased; and the mixture became in

[1] Moor: "The Discovery of Ureine, the Principal Organic Constituent of Urine." THE MEDICAL RECORD, 1900 (Sept. 22d), lviii. No. 12, p. 471.

reality more toxic. We fail to see, therefore, how chemical purity was approached by such awkward steps as these. We purposely followed Dr. Moor's directions in detail here, however, merely to obtain results that would be comparable with his. Very heavy precipitates formed on the addition of the reagents, showing how large was the proportion of inorganic substance in the ureine which its discoverer pronounced "sufficiently pure to satisfy all exigencies of clinical medicine and of physiology."

Finally, in the preparation of pure (?) ureine, as Dr. Moor directs, coloring matters were removed with mercuric nitrate. Much of the residual urea and other organic substances, as well as coloring matter, were precipitated from the mixture by this substance. At first the precipitate with mercuric nitrate dissolved in the mixture, but eventually became permanent. In order to avoid excess of mercury (Dr. Moor gives no suggestion in this connection), addition of the nitrate was discontinued when nearly all color was removed and only very slight precipitation was still obtainable. The bulkiness of the precipitate at this point, as well as its appearance, further emphasized the absurdity of considering the previous fluid anything but a mixture. The final liquid was decidedly acid in all cases, as all the filtrates had been from the beginning. According to the original paper, Dr. Moor neutralized with sodium carbonate at this point. "It is advisable then," he says, "to add a sufficient amount of sodium carbonate, so as to render the liquid slightly alkaline." After all this he described ureine as a "very slightly alkaline, almost neutral," substance. Was its reaction just what Dr. Moor made it? In his second communication Dr. Moor says, why we do not know, "It is better not to neutralize subsequently with sodium carbonate." Consequently, though he does not say so, ureine would have to be an acid substance, if purity had been attained by the procedure he has outlined.

The decolorized ureine was finally evaporated at 48°–50° C., to remove water, and then was carefully analyzed qualitatively. Employing customary methods of separation and detection, "purified" ureine was found to contain sodium, potassium, ammonia, phosphate, urea, creatinin, pyrocatechin, phenol, alkaloidal substances, and nuclein bases. Other urinary substances were present which we did not attempt to identify. In spite of the fact that we avoided excess of mercuric nitrate in the process of decolorization, we always found mercury in ureine. Doubtless a soluble organic compound of mercury that had formed with the nitrate was its immediate source. Nitrate and oxalic acid, also introduced during Dr. Moor's process of "purification," were constant constituents. Bluish to brownish amorphous material separated as the fluid concentrated after decolorization. Shaken up repeatedly with ether during a period of three months, ureine separated gradually into four permanent layers of different color and varying degrees of transparency, and the ether itself became slightly yellowish. Samples that had been allowed to stand exposed to the air for three months, deposited crystals of urea. The mother liquor yielded additional crystals when its temperature was reduced to, and held at, 0° C. Under these conditions the fluid became semi-solid, so large was the proportion of crystalline material.

Dr. William A. Taltavall, who has had considerable chemical experience in this laboratory with urinary extractive bodies, analyzed several of our preparations and favored us with some of the qualitative data just presented. Mr. A. N. Richards, assistant in physiological chemistry, has also given us valuable help in this connection. We cordially thank both of these gentlemen for their able co-operation.

In a special series of preparations designed to determine the influence of variations of the method, we obtained the crude ureine from forty-nine litres of urine, and then, dividing it into two equal parts, decolorized one half with mercuric nitrate, the other half with plumbic acetate. Since the deductions in Dr. Moor's first paper were based on the qualities of neutralized ureine, we neutralized with sodium carbonate one half of each quantity of the "purified" ureine. That is, of the portion decolorized with mercuric nitrate, one half was neutralized ("M—2"), the other was not ("M—1"). In the same way, one half of that decolorized with plumbic acetate was neutralized ("P—2"), the other remained acid ("P—1"). "M—2," "P—1," and "P—2" solidified after evaporation at 45° C. for about a week, because of crystallization of urea and inorganic matter. They were unlike in appearance and hardness; "M—1," a thick oily fluid at this stage, seemed to contain the least quantity of solid matter, and to hold the smallest amount of crystalline substance in suspension.

The appended table (results in duplicate) shows the loss in weight of samples of each of these preparations, after having been at higher temperatures for prolonged periods; also the ash of each:

Preparation.	Weight of Urine Taken.	On Water Bath 50 Hours.	Total Number of Days in Air Bath at 100–110° C.			Weight of Ash.
			3½.	10½.	25.	
	Grams.	Grams.	Grams.	Grams.	Grams.	Grams.
M—1	3.90	3.36	2.63	2.25	1.88	0.1788
	3.94	3.37	2.64	2.23	1.96	.1818
M—2 (neutralized).	6.49	5.51	4.47	4.02	3.58	.8137
	7.63	6.66	5.49	4.82	4.10	.9566
P—1	5.65	5.03	4.16	3.79	3.41	.3562
	6.80	6.02	5.17	4.73	4.21	.4231
P—2 (neutralized).	5.12	4.58	3.81	3.53	3.08	.7590
	6.09	5.51	4.70	4.33	3.69	.7888

The following figures represent the loss of substance, at the end of the drying process, both in amount and in percentage, of original ureine; they give, also, the proportion of ash in the ureine and in the final dried residue:

Preparation.	Total Loss of Substance.		Percentage of Ash in:	
	Amount.	Per Cent.	Original Ureine.	Final Residue.
M—1	2.02	51.80	4.51	9.51
	1.98	50.25	4.61	9.27
M—2 (neutralized).	2.91	44.84	12.54	22.73
	3.53	46.26	12.53	23.33
P—1	2.24	39.65	6.30	10.44
	2.59	38.09	6.22	10.05
P—2 (neutralized).	2.04	39.84	14.82	24.64
	2.40	39.41	12.95	21.36

These results show at a glance that ureine, as our qualitative results proved, is not a definite chemical substance, and indicate that with comparatively unimportant modifications of method it varies greatly in composition. If it were "a body belonging to the group of alcohols of the aromatic series," we should expect to find little or no residue after such vigorous heating for so long a period. Except that they were viscid rather than fluid, and a little darker in color, some of the final products were the same in appearance as the original mixture and seemed little affected by the heating. If "at a temperature of about 80° C. it (ureine) begins to split into several bodies belonging to the class of aromatic oxy-acids," what organic sub-

stance, may we ask, is left behind that is so resistant to this destructive action of a temperature of 100°–110° C.? There was, of course, some decomposition of contained organic products; but, we believe, most of the loss represented in the above tables was due to elimination of water. The figures in the tables are valuable, then, for the suggestion they make that ureine is a mixture.

In his second communication Dr. Moor says: "If we add nitric acid to ureine, a solid waxlike mass will be formed at once, and this is a fact worth remembering, as otherwise one might think that this solid, waxlike substance was the result of a chemical combination of nitric acid and urea." In all probability it was. This waxlike mass could be obtained immediately with concentrated nitric acid in all of our ureine preparations. When it was broken up mechanically in an excess of concentrated nitric acid, and examined under the microscope, this mass was found to consist almost solely of urea nitrate crystals. Diluted somewhat, each sample of ureine gave an abundant yield of crystals of urea nitrate and urea oxalate, with the corresponding concentrated acids.

We cannot agree that "it is this constitutent (ureine) of urine which is the cause of its specific odor." The longer the period of evaporation in preparing ureine, we have found, the less distinct is the odor remaining with it. The ability of ureine "to take up large quantities of oxygen with great facility" is doubtless equivalent to the total capacity of its various constituents to do the same. The reaction with potassium ferricyanide and ferric chloride given by ureine may be attributed, in part at least, to the reducing substances we have found in it.

Dr. Moor's statements regarding the amount of ureine in urine, and also its specific gravity, cannot be credited. Our own experience in comparative observations shows that each is determined largely by the length of the period of evaporation in preparing ureine. The more prolonged the evaporation, after the time that vapor no longer can be seen arising from the fluid, the less is the volume, and the greater the weight, of residue (ureine).

With respect to the toxicity of ureine, upon which Dr. Moor lays so much stress, and its consequent influence in uræmia, little need be said in view of the chemical facts we have just presented. We tested this matter, however, in two experiments. In the first, in a healthy dog weighing 5 kgm., subcutaneous injection of 8 c.c. of "purified," concentrated ureine caused great restlessness, diarrhœa, diuresis, and vomiting during the first twenty-four hours. Marked local irritation and œdema about the point of injection also resulted. There were no convulsions at any time; no suggestions whatever of uræmia. The dog was chloroformed on the third day after injection.

In the second experiment, on a lively cat weighing 2 kgm., subcutaneous injection of 4 c.c. of the same preparation of ureine, after it had been further concentrated at 45° C. for forty hours, caused marked local irritation and was followed at once by restlessness; later by diuresis, diarrhœa, vomiting, paralysis, and finally by death in convulsions, nine hours after introduction.

The results of our second agree in the main with those of the single experiment, reported in detail by Dr. Moor, on a rabbit with "3½ c.c. of ureine obtained from the urine of a pregnant woman in the ninth month of her pregnancy." We are unable to say, however, that any single symptom exhibited in our experiments was due to any one definite chemical compound in the mixture Dr. Moor terms ureine. The poisonous action of ureine is doubtless due to the sum of the toxicity of the normal urinary compounds contained in it.

The fact has long been known that the normal urine contains substances of a very toxic character.[1] Potassium compounds, as all of our readers know, are prominent among these; but even more poisonous are the various organic bodies of an alkaloidal nature, present in only minute proportion. Dr. Moor's method of preparing ureine fails to eliminate completely either potassium salts or the normal basic alkaloidal bodies giving the typical reaction with potassium ferricyanide and ferric chloride, and the toxicity ascribed to ureine must undoubtedly be referred, in part at least, to these substances dissolved in it. The evaporation process from the beginning, it is perhaps needless to point out, causes an accumulation in ureine of these various products possessing toxic influence.

Summing up in a few words: Ureine is not a chemical individual. It is a *mixture* containing several of the organic substances and a considerable proportion of inorganic salts ordinarily found in normal urine. Further, its toxicity can be referred to some of these normal urinary constituents. Consequently, our knowledge of the cause of uræmia, we regret to say, has been in no way increased by Dr. Moor's work on ureine, nor can any of his deductions regarding the biological significance of this urinary complex be accepted.

A METHOD OF REDUCING DISLOCATIONS OF THE THUMB.[2]

By JOHN F. ERDMANN, M.D.,

CLINICAL PROFESSOR OF SURGERY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE OF NEW YORK.

It is a source of regret on the part of the writer that a definite cause of irreducibility in these cases cannot be assigned. In looking over the English literature from 1800 to 1899 the author has found the following various lesions given as causes of non-reduction:

The tendon of the flexor longus pollicis was lodged between the heads of the articular surfaces by winding round from the ulnar side in a case reported by Woodsworth in the London *Lancet* of 1863. He says reduction should be accomplished in these cases by rotating the distal portion inward and outward, followed by hyperextension and then flexion. Another attributes all evil influences to the lateral ligaments, and advises cutting them for reduction.[3] Another, and a very frequently assigned cause, is the flexor brevis pollicis, the heads being locked behind the metacarpal bone.

FIG. 1.—Dorsal Displacement.

J. W. Elliott[4] reported a case in which the bone was grasped between one of the heads of the flexor brevis and the tendon of the longus, and that in this case all

[1] The latest reference to the matter that we have seen is the recent paper by Dresbach, confirming the previously accepted general fact, without, however, isolating or identifying any active substances: "On the Toxicity of Normal Urine," The Journal of Experimental Medicine, 1900, v., p. 315.

[2] Read before the Society of Alumni of Bellevue Hospital, January 2, 1901.

[3] Taafe: London Lancet, 1873, vol. i., 300.

[4] Boston Med. and Surg. Journ., 1887, vol. cxvii., 625.

the ligaments were torn; demonstrated by operation for reduction. The sesamoids in the short flexor have also received a large share in this discussion. Louis Stimson, in his excellent work on "Fractures and Dislocations," assigns the cause to the anterior ligament with the following words: "The cause of this difficulty (in reduction) in all cases in which he exposed the joint, has been the torn edges of the anterior ligament, closely drawn across the back of the metacarpal behind its edge, and a slight nicking of that edge made reduction easy."

Personally, the author has no theory or demonstration to prove any cause, but feels that we must accept all causes that have been given, as each has by actual operative procedure been demonstrated as a factor in this class of injuries.

Neither do I claim any priority for the method which I shall describe, for in the literature of 1853 John Doe, of Vermont, reported a method[1] that bears a slight relationship in procedure, but he deemed it advisable to make sharp extension before manipulating. This method will be referred to later. Before describing the writer's method, some of the procedures advised and used during the nineteenth century will be briefly cited.

Fig. 2.—Volar Displacement.

Vidal's method, recommended by Roux and the French authors, consisted in slipping the handle of a large door key over the distal extremity of the thumb and using it as a means of traction, etc.

The Indian puzzle, as a means of traction, was recommended by Hamilton, of Buffalo. This is a cylinder of some woven fibre which was slipped over the distal end of the thumb, and as traction was made, the puzzle grew smaller in size and thereby gripped the thumb more forcibly, allowing of a great amount of force to be applied.

Levis' apparatus, unearthed now and then from the splint-box in many hospitals, I feel sure you are all familiar with. This was advised by Levis in the *American Journal of the Medical Sciences* of January, 1857.

The clove hitch, made of tapes, was another method of securing a firm grasp on the distal portion of the thumb.

The forceps of Blandin and Charrière was an instrument with two concave blades and powerful handles, the object being to grasp the dislocated portion firmly and allow of powerful traction.

It is needless to say that the employment of these instruments and devices has been followed by evulsion of the dislocated portion and even including muscular and tendon detachment.

Tatum in 1850 reported a case in which he excised the articular surface in a case of compound dislocation, infection taking place and amputation at the mid forearm resulting.

Subcutaneous cutting of the lateral ligaments was done with good (?) result by Taafe, the case being reported in the London *Lancet*, 1873, vol. i., 300.

B. Cutter[2] in 1858 reported a case of dorsal dislocation reduced by the Crosby method. This case, he stated, was held by the lateral ligaments.

A. B. Hirsch[3] reports two cases reduced by the Crosby method plus bilateral extension to liberate the lateral ligaments. These cases were distal phalanx dislocations.

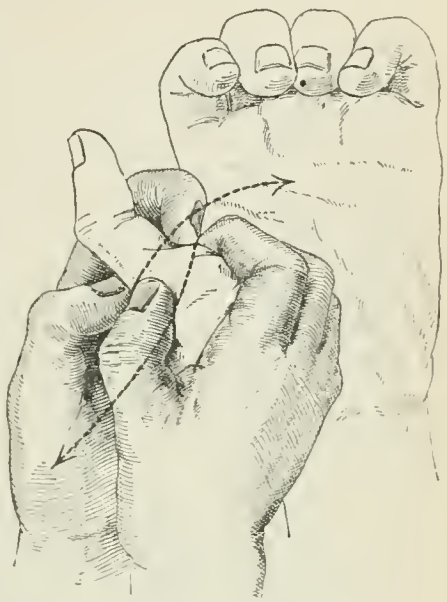

Fig. 3.—Reduction in Dorsal Displacement.

Crosby's method was thus described. The thumb is hyperextended by one hand of the operator, while the thumb of the other hand of the operator forces the phalanx in place by pushing on the phalangeal base. This was known as Crosby's right-angle motion.

Crosby's method with rotation has been used successfully. J. F. Helber[2] advises—on the theory of the cause of irreducibility being the heads of the short flexor—the use of a tenaculum to pull the flexor heads or tendons out of the way. He cited no case.

John Doe,[3] of Vermont, describes the following method: Place the patient's hand upon the knee, facing in the same direction as the patient, extend the thumb to a right angle, place the index finger on the ball of the patient's thumb, the operator's thumb on the back of the dislocated phalanx, and push forward.

You will note the differences in the method described by the writer, and to make the method more clear the author presents four illustrations. Figs. 1 and 2 show dorsal and volar dislocations of the metacarpophalangeal articulation. The dorsal does not show as well as the volar; both could be more marked, but owing to the subjects being frozen the artist was hampered in reproducing the actual conditions in his illustrations.

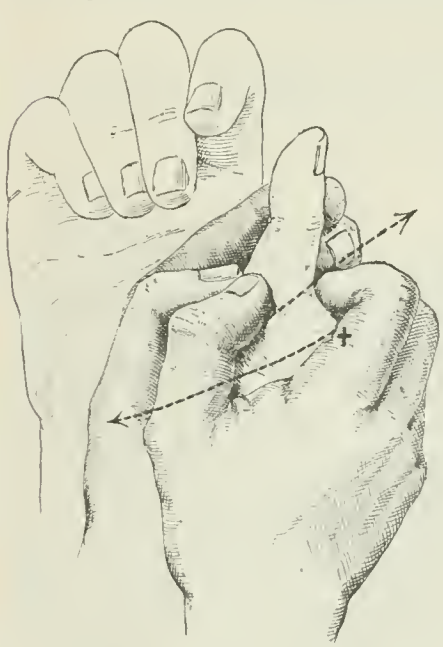

Fig. 4.—Reduction in Volar Displacement.

Figs. 3 and 4 show the method used. In Fig. 3, *i.e.*, in cases of dorsal displacement, the operator places his thumbs at the base of the proximal phalanx and the cushions of his

[1] American Journal of the Medical Sciences, vol. xxv., 401.
[2] The American Journal of the Medical Sciences, vol. xxxv., p. 561.
[3] Philadelphia Polyclinic, 83, vol. i., p. 40.

[3] American Journal of the Medical Sciences, 1853, vol. xxv., p. 401.

index fingers on the distal extremity of the metacarpal bone. The forces are then applied in opposite directions, as shown by the curve of the arrows, *i.e.*, the index fingers pull the metacarpal bone in a condition of extension or abduction, while the thumbs raise and push the phalanges in a position of flexion. Should the dislocation be volar, which is rare, the procedure with reference to the operator's thumbs and index fingers is reversed, the thumbs lifting and extending the distal phalanges, and adduction or flexion of the metacarpal bone is made by the index fingers, as shown in Fig. 4, although the fingers should be placed lower than shown in the cut, so as to cover the prominence now seen at +, and the thumbs should be placed at the proximal end of the arrow pointing upward.

This method has been used by the author since 1887, and so far no failure in reduction has been met with. The citation of one case will be sufficient.

X——, aged thirty years, a male nurse in a sanatorium for insane and alcoholics, was attacked by his patient with a chair, and in attempting to ward off the blow received the impact upon his right thumb, and sustained a complete dorsal displacement at the metacarpo-phalangeal articulation. He was seen several hours afterward by a prominent surgeon, who made protracted efforts at reduction and finally suggested ether anæsthesia with operation. The patient objected and called in the neurologist in charge of his patient, who sent for the author. The signs were quite evident, although considerable swelling was present. The patient willingly submitted to a trial without anæsthesia, and upon the first attempt reduction was accomplished. A like experience resulted in a case of dorsal displacement in the mid-phalanx of the middle finger on the left hand in charge of another interne, during the writer's hospital interneship in 1887. Anæsthesia was required in but one case in this entire time.

Although the writer has not met with a failure up to date, no claim is made for infallibility, but he does claim that a fair trial will demonstrate the ease of reduction, and that anæsthesia and the cutting operations in this injury will be markedly decreased.

TUBERCULOSIS IN PRISONS AND REFORMATORIES.

By S. A. KNOPF, M.D.,

NEW YORK.

A few months ago I received from the distinguished secretary of the Indiana State board of health, Dr. J. H. Hurty, a letter speaking of the Indiana State reformatory in reference to a "most interesting tuberculosis situation" existing in that institution. The following are the facts which Dr. Hurty communicated to me: "This reformatory is in reality a prison for males, but no one over thirty years of age is confined there. In 1899 the legislature appropriated a quarter of a million dollars to build a new cell-house, containing six hundred cells. During the construction of this cell-house it was necessary to provide for the prisoners in the old cell-house, and temporary forced ventilation was provided. A space, however, formerly intended for two hundred is now crowded with almost six hundred, and the consequences are a rapid increase in tuberculosis. There are now not less than two hundred prisoners with the disease, all forms of which abound. Meningitis has killed a few and general tuberculosis is very common. This reformatory is situated at Jeffersonville, Ind., immediately opposite Louisville."

The other day I was honored by a visit from Mr. Charles F. Wingate, the eminent sanitary engineer of New York, in order to consult with me about the alarming tuberculosis situation now prevailing at Sing Sing.

Charities, the official organ of the Charity Organization Society of the city of New York, devoted in its number of January 19th an entire column to the subject of tuberculosis in the Elmira reformatory. I cannot do better than quote textually the interesting and instructive report of the board of managers of the Elmira reformatory, for the year ending September 30, 1900, as it appeared in *Charities*:

"For a number of years tuberculosis has been an increasing and dangerous feature among our prisoners. Many have it upon arrival, in a more or less advanced stage, others develop it under the trying conditions of prison life, with cellular confinement, and association with those already affected, and all unite in communicating the subtle and poisonous infection to their clothing, their bedding, and the air of the cells and corridors. The management further became convinced, by careful scrutiny, extending over many months, that prisoners, healthy on arrival, became affected, and sometimes with astonishing rapidity, by the disease, from being steadily confined in the same cell with a tuberculous subject.

"Inquiry showed that . . . no intelligent and complete analysis of the prison population for the purpose of separating the diseased from the healthy inmates had been undertaken, and no orders existed, nor was it the practice to exclude from the buildings civilian employees in whose families were contagious or infectious disease, such as measles, scarlet fever, or diphtheria, while such disease prevailed."

This renewed awakening to a danger to which I endeavored to call attention in several of my previous writings,[1] is gratifying to me, and to stimulate, if possible, a more widespread agitation for reform in this respect is the object of this article. To those familiar with the subject the above revelations are not new. Prisons all over the world have had for years the reputation of being the breeding-places of tuberculosis. Observations in this respect date back as far as 1825, when Baly[2] began to gather his statistics concerning the Milbank penitentiary in London. From these we learn that from 1825 to 1842 175 deaths occurred in this institution, of which no less than 75 were due to consumption. Besides these 75 cases 90 prisoners were set free during these seventeen years on account of being hopelessly afflicted with pulmonary tuberculosis.

Villemin,[3] to whom we are indebted for the first absolute proofs of the infectiousness of tuberculosis, shows that the mortality from consumption in French prisons was three to four times as great as that of the free population. Pietro Santa, also a French observer, reported that out of 27 deaths in the "prison civile" of Algeria 17 were due to consumption, and in the Central prison of Harrach no less than 57 deaths out of 153 were due to the same disease. Baer,[4] who investigated the condition of German prisons, published the following interesting facts: "During the first year of confinement 38 out of 100 deaths were due to tuberculosis, during the second year 45, during the third year 42, and during the fourth year 36." These statistics perhaps help to demonstrate that a great majority of consumptives among the prisoners have contracted their disease during the time of their confinement.

Now let us, in the light of our present bacteriological knowledge of tuberculosis, as well as with the aid of what our fathers taught us of the non-bacterial causes of consumption, enumerate, if possible, all the reasons for this fearful mortality among prisoners in nearly all penal institutions, in this and in other countries, and learn therefrom what may be done to remedy the conditions. I have myself in an inofficial position visited some prisons in this and in other States. What surprised me in some was the absence of spittoons and the absence of regulations concerning expectorating. Now, I venture to say there is not a prison of any size where there are not at least a few tuberculous prisoners. They may not be known as such to the prison authorities, but they exist nevertheless, and with no spitting regulations, no spittoons, they certainly constitute constant centres of infection. But even should there be spittoons and should spitting regulations be observed religiously by the inmates, there still remains the drop infection. This method of infection, while of much less importance in the average free patient than in the tuberculous prisoner, must, in my humble opinion, be considered one of the very important manners of propagating the disease in prisons. The little drops of bacilliferous saliva, expelled during the so-called dry cough, loud speaking, sneezing, etc., fall to the ground before they reach a distance of more than three feet. The trained free patient will keep his handkerchief before his mouth during dry cough or sneezing, nurses and friends can be taught not to approach the patient unnecessarily close or long, and the danger of drop infection can thus be reduced to a minimum. In a cell, often not much wider than three feet, occupied by two prisoners, drop infection is rendered easy, and if one of the inmates is tuberculous the other will surely contract the disease, leaving aside the additional causes which foster tuberculosis in prison life. Drop infection is not only possible in the cell, but just as much and perhaps more so when the prisoners sit or stand close together, or face each other at the work table. It is also possible when they march lock-step, as they are then even closer together than when at work, though perhaps the infection of the prisoners' clothing plays here the most important part.

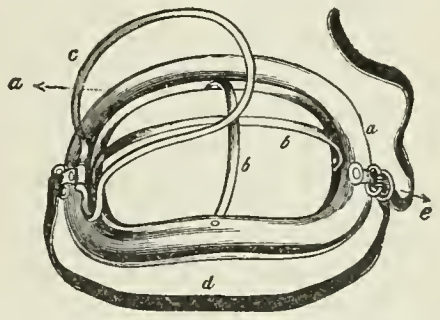
As a final evidence of the fact that the healthy prisoner is very often directly infected by his tuberculous cell-mate, we must mention yet the statistics of Döderlein and others, published in Cornet's recent book,[1] according to which the mortality from tuberculosis among the prisoners condemned to solitary confinement is considerably less than among ordinary prisoners.

So much for the infection by the inhalation method. The possibility of infection coming from imperfectly disinfected cells, clothing, bedding, mattresses, etc., used previously by a tuberculous individual, must, however, also be thought of. We will not speak here of ingestion and inoculation of tuberculosis. Prisoners are no more exposed to this mode of infection than others, but let us rather seek the causes which render the individual so very susceptible to the germs of tuberculosis during the average prison life.

As a primary predisposing cause to consumption during prison life we must, of course, consider the lack of fresh air. I have learned that there are some prisons in which one hundred and fifty cubic feet only are allotted to each pair of prisoners for the night, which means seventy-five feet per individual. The work-rooms may offer more cubic space, but we have here the additional dust from the material worked with. If tuberculous patients are employed in the workshops, which at the present time is very likely in the majority of prisons, the dust will have its large admixture of tubercle bacilli.

[1] Cornet: "Die Tuberkulose," Berlin, 1899.

Next to the lack of fresh and pure air we might mention as a predisposing factor the prison fare. In view of the exceilent reputation our American prisons have in this respect, it would be unjust to say that all prisoners are underfed. This is not so, but there are some prisons where an improvement in the food, in its selection and preparation, would tend to decrease the morbidity and mortality from tuberculosis. The condition of the buildings and the soil on which they stand are not infrequently the cause of rendering tuberculous disease, so to speak, endemic in these institutions. It is well known that damp soil fosters tuberculosis. A prison situated on damp ground is always in danger of having more tuberculous patients than one built on dry soil. The material, too, used for the building of prisons has a great deal to do with the sanitary conditions. I am indebted to Mr. Wingate, the above-mentioned sanitary engineer, for the interesting information that the walls of our prisons made entirely out of stone tend to retain moisture and cold more than any other building material, and thus



ipso facto help to foster tuberculosis almost as much as does damp soil.

Another important factor, tending to create a favorable soil for the invasion of the bacilli in an individual condemned to prison life, is a psychic one. The mental depression of many prisoners is well known; it may be due to remorse, nostalgia, love of liberty, or to all these. Many prisoners are constantly sad. In sorrow one eats but little, the arterial pressure is low, the muscular weakness and depressed nervous state make the act of breathing incomplete. The heart is called on to do more work and perpetual palpitation ensues. The circulatory disturbances in the lungs impair the nutrition of this organ, and thus this field for the invasion of the bacillus of tuberculosis is prepared.

After having studied the causes let us try to seek the remedy. The most rational one which suggests itself to one's mind would be that there should be special prisons for tuberculous criminals as there are for the insane criminals. Such a rational change of the situation may not be brought about so easily, and it might be more practical to seek remedies which can be applied immediately.

The tuberculous prisoner must be separated from the non-tuberculous in the workshop as well as in his cell. This can be done and should be done. Every prisoner upon entering the penitentiary or reformatory school, or only the detention prison, should be carefully examined physically in addition to the bacteriological examination of the sputum. Every inmate of any of these institutions should be re-examined once every three months. This examination should not be confined to prisoners alone, but should be obligatory for wardens, keepers, officials, and help.

How the local division of tuberculous and non-tuberculous prisoners can best be effected will depend very largely upon the situation and the capacity of the institution and should be supervised and directed by the medical officer of the institution. An officer or an employee of the prison, if found to be tubercu-

lous, should in his own interest leave the institution, seek if possible the best hygienic surroundings, and submit himself to thorough treatment.

What is to be done in the line of treatment of tuberculous prisoners must also depend upon the location of the prison and the means at the disposal of the authorities. To form convict camps, an experiment tried in Alabama, might be productive of a great deal of good; but what it is best to do with tuberculous prisoners in the various stages of the disease is still a problem requiring a good deal of study. One thing is certain, in the interest of their own welfare as well as that of the community at large, tuberculous prisoners should be separated from the others. The clothing of the prisoners, but more particularly that worn by tuberculous individuals, should be regularly disinfected. The same rule also holds good for bedding, mattresses, etc. No matter whether there are tuberculous patients or not, there should be spittoons and spitting regulations in all prisons. Cheap pocket spittoons might be perhaps most suitable. Every inmate, whether tuberculous or not, should be enjoined never to expectorate except in his individual flask.

Prisoners should also be taught always to hold a handkerchief before their mouths during sneezing or coughing. In short, the discipline to avoid drop infection and infection from carelessly deposited sputum in a prison should be equal to that of the best conducted sanatorium for consumptives. Such precaution would not only tend to diminish the danger from the expectoration coming from individuals suffering from tuberculosis, but prove also of great prophylactic value in epidemics of grippe, measles, whooping-cough, etc. To avoid drop infection, prisoners should be about four feet apart when in the workshop, and whenever practicable each one should have his own cell. Whenever from lack of room tuberculous prisoners cannot be separated immediately from the others, and where even the workrooms are so crowded that the prisoners cannot be placed at least three feet from each other, the tuberculous inmates of the institution should wear mouth masks. Such masks, of which I give an illustration here, were first introduced by Prof. B. Frankel, of Berlin, in his division of the Charity Hospital of that city. There all the tuberculous inmates must wear these masks to catch the germs they expel in speaking and coughing, and are allowed to remove this protector only while eating or expectorating. In Professor Frankel's clinic, as also in others where this custom has been imitated, the patients have soon become accustomed to the use of the mask. It seems to me that in a prison, where discipline is still more easily carried out, such measures could be beneficially installed. By impregnating the gauze, which is held in place by the metallic frame of the mask, with some medicinal substance, the tuberculous prisoners could be made to believe that the instrument was worn for their own personal benefit instead of for the benefit and protection of others, or, as they might think, as a means of designating them as individuals suffering from a contagious disease. Thus, even the humane arguments for not using such a mask would have no foundation. Where these masks have been used, bacilli have been found almost constantly on the gauze. Frankel's and Moszkowski's experiments[1] have demonstrated the great value of these protective masks, which can be easily disinfected. The gauze should, of course, be changed at least once a day and immediately be burned after removal. Plumbing and ventilation throughout the prison buildings and especially in workshops and cells should be made as perfect as possible, and the cubic space allotted per individual at night time be at least three hundred to four hundred feet. Great attention should be paid to the good condition of the sewerage system. No prison should be erected on damp soil, and the material serving for its construction should not be such as to retain cold and dampness. When in the opinion of the prison physician a change or betterment of food is indicated, in order to preserve the health of the prisoner, his request should be complied with. Wherever practical, outdoor work should be sought for the prisoners, but at least a few hours of outdoor exercise every day should be made possible for the well-behaved prisoner.

To counteract the mental depression to which so many prisoners are subject, I know of no better remedy than the multiplication of prison angels. The sermons preached on Sundays in the prison chapel are doubtless always of a beneficent influence, but they do not reach the individual in the same measure as the gentle words of our woman prison angels.

In conclusion, I wish to say to those who think that tuberculosis among the criminal class should be regarded rather as a blessing, since it exterminates an undesirable element in society, that all criminals are not criminals for life. The majority of them do not remain in prison, but return to live again in our communities, mingle with us as other people, and if they are tuberculous they not only can transmit the disease to others but also can become a burden to the community. Therefore, putting aside all sentimental reasons why we should combat tuberculosis among the inhabitants of prisons as well as among other people, we should do it in the interest of the healthy prisoners who may again become useful members of the community, and in the interest of the people at large.

[1] Frankel: "Die Tröpfchen-Infection der Tuberkulose und ihre Verhütung."

Acute Pulmonary Œdema.—J. Teissier (*Wiener medicinische Blätter*, November 1, 1900) concludes as follows: (1) Even severe and sudden mechanical disturbances are not in themselves, as a rule, capable of producing pulmonary œdema. The experiments of Cohnheim and Lichtheim have already shown that ligation of the aorta below the diaphragm or ligation of the pulmonary veins might be accomplished without producing pulmonary œdema; in my experiments complete and continued compression of the anterior and the entire aorta in dogs has been produced, without giving rise to pulmonary œdema, except when this compression was carried to such a height that the pressure in the pulmonary artery was tripled and of sufficient degree to force out the trocar. (2) If to such a mechanical disturbance there be added an irritation of the cardiac plexus (compression of the left ventricle or auricle or irritation of the peripheral vagus stump), then we can see mild disturbances in the carotid and pulmonary arterial pressure, that is, simultaneous elevation of both pressures with the maximum in the pulmonary; with this there occurs a slight œdema, which appears in streaks on the surface of the parenchyma and especially at the basis of both lungs. These streaks signify hepatized or atelectatic areas, produced by intra-alveolar transudation around which circumscribed zones of compensatory œdema develop. (3) The œdema is permanent and widespread only when the animal is given a preliminary intravenous injection of 1–7 c.c. of methyl salicylate. (4) This previous intoxication appears both experimentally and clinically to be the first step in the production of acute pulmonary œdema; it may give rise to an enormous œdema, without any unusual modification of pressure in the left ventricle or pulmonary artery. It was easy to determine that acute œdema could be readily produced experimentally, without any marked change of pressure in the left ventricle.

MEDICAL RECORD:

New York, March 2, 1901.

THE NEED FOR MORE EFFICIENT SANITATION.

THE problem above all others which awaits solution is not how to invent the most deadly weapon of offence or defence, nor to evolve the best means of living cheaply, nor to discover a specific for each and every disease; nor is it in the sphere of high politics; but the problem is to devise the most effective methods of improving the sanitary conditions of cities and of teaching and enabling the poorer classes throughout the world to lead a healthy life—in short, to endeavor to banish disease by rational preventive measures. It would be superfluous here to do more than point to the curtailment of disease already brought about by various modes of thorough sanitation intelligently carried out. Suffice it to say that the results have been so illuminating that they have shed a bright light upon the possibilities of the future, and have acted as a beacon for the guidance of social reformers. The question of sanitation, however, is such a wide one that within the limits of an article it will be possible to deal with only a few of its more salient features.

At the Pan-American Congress just held in Havana, Dr. Walter Wyman, surgeon-general M. H. S., gave an able address on the subject, and especially urged that municipalities should more fully recognize their responsibility and their duty to the community by insisting that the cities and towns under their control should be kept clean and wholesome throughout; and he rightly drew attention to the fact that in order to bring about this state of affairs it will be necessary to cultivate among the people a demand for municipal sanitary excellence, and as great an abhorrence of municipal filth and neglect of sanitary engineering as there is of uncleanly dwellings and of uncleanliness of person. A good water supply, perfect sewerage, and proper disposal of garbage, good street paving and street cleaning, should be the first boast of every municipality. But these are no new truths; and although it is perfectly right that they should be constantly ventilated, and that, if possible, the mass of the people should be educated to appreciate their full significance, and while at the same time thinking persons of all grades of society have come or are coming to a belief in the virtues of proper municipal sanitation, and take a pride in the beauty of the town in which they live, yet the difficulty is that the real root of the evil is not grappled with, and that the localities in which disease is nourished and the sources from which it is spread far and wide are too often untouched. As Dr. Wyman pertinently remarks: "There is no reason whatever for the existence of slums in any city. Relatively speaking, too much attention is paid to public parks and handsome municipal buildings. The city's improvements should be in the alleys, around the docks, in the tenement-house quarters; and great as may be the appreciation of public art as manifested by statues and public gardens, and of the parks and boulevards, let these wait upon the less showy but more important features of municipal life. The old saying, 'What the eye does not see the heart does not grieve for,' applies with equal force to cities as to individuals.

"The faults that do not obtrude themselves upon the observation are by the majority of people passed by heedlessly. The plague spots of large centres of population are invariably in out-of-the way places. Therefore the sewerage, paving, light and ventilation of these, the worst sections, should receive the first and most constant attention. Unfortunately it is notorious that this is not the case, and the energies of the municipal authorities are for the most part concentrated upon the effort to keep the principal thoroughfares in a satisfactory sanitary condition to the neglect of the disease-breeding purlieus. The wealthy and presumably better-educated portion of the community display in this connection a lamentable lack of foresight, and their apathy with regard to the unsanitary conditions of the districts inhabited by the poor classes in many instances may be termed almost suicidal." Dr. Wyman puts the situation plainly when he says: "It is an interesting matter for conjecture—What would be the effect upon the prevalence of contagious disease if there could be a complete wiping out of all slums and low tenement-house districts in all our cities? It matters not that an epidemic once started may prevail as violently or more violently in the better portions of a city, and that cleanliness and sanitation may then have but little effect upon its progress. The fact remains that for the perpetuation of these diseases among the people filth and bad environment are essential; and when we reflect how easy and natural is the upward gradation of infection, how readily through successive grades it may ascend the social scale from the lowest to the highest, the direct and personal interest of the wealthy and more intelligent classes of a community in the condition of the poor and ignorant becomes manifest." The fact is that well-to-do citizens are both directly and indirectly concerned with the physical and moral welfare of their poorer brethren, and that a failure to realize their true position in the matter will inevitably recoil disastrously upon their own heads. The men of almost unlimited wealth, "rich beyond the dreams of avarice," who are more numerous in this country than in any other, and who, to their credit be it said, are as a class by no means backward in furthering charitable schemes, seem not as yet to have become impressed either with the need of or with the good to be done by assisting with their money the cause of efficient sanitation.

In Europe and in Great Britain especially, many philanthropists of ample means have expended large sums in improving the dwellings of the poor, with on the whole most satisfactory results. The writer of the address to which reference has been made comments upon the immense amount — $61,000,000 —which has been contributed during the past year to educational, religious, and charitable objects and institutions in the United States, and makes the just reflection that while such lavish benevolence is a magnificent manifestation of prosperity and philanthropy combined, yet in the list of benefactions there is no mention of purely sanitary gifts or endowments. He is of the opinion that more practical and beneficial results would have been obtained if this $61,000,000, instead of being expended upon educational, religious, and charitable institutions, had been devoted to reclaiming the slums, and in the purchase and destruction of rookeries, with the erection in their stead of modern sanitary tenement houses; and that, too, even though the money had not been expended outright as a gift, but as a safe though moderately paying investment. In the MEDICAL RECORD the evils of the tenement-house system, as present in New York and many other American cities, have been frequently discussed, and it has been argued that these cities should follow the example of London and other European towns in demolishing on a wholesale scale dwellings constructed on such principles, and in building houses in which human beings may live as human beings and not as cattle. The tendency of up-to-date treatment of disease is rather to prevent than to cure. The policy is assuredly a wise one. But so long as districts reeking with filth, overcrowded, lacking light, air, and ventilation, are allowed to exist, the hope of stamping out or even checking disease to any great extent must be dismissed as Utopian. Sanitation carried out thoroughly and rigorously is the only panacea.

THE REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE report of the surgeon-general of our army increases each successive year, both in the quantity and in the importance of the information therein contained. That this must be so will be readily understood when it is considered that the army is much larger than ever before, while it is more widely scattered than was formerly the case. Indeed, with the possible exception of the soldiers of Great Britain, the fighting men of this country are located at the present time in lands more distant and in climates more various than are those of any other nation.

Necessarily the opportunities provided the United States military surgeons of studying injuries and disease are on a correspondingly extended scale.

The report of the surgeon-general of the army for the year ended June 30, 1900, is without exaggeration an extremely valuable document, and one from which the ordinary medical practitioner can gather a multitude of useful points. The report states that during the calendar year 1899 there were 229,885 admissions to sick-list recorded in a mean strength of 105,546 regulars and volunteers. This is equivalent to a rate of 2,178.06 per thousand of strength as compared with 2,146.18 per thousand during the year 1898, and with 1,236.66 the mean annual rate of the decade 1888–97. Of the admission rate for the year, 714.99 were constituted by malarial diseases, 380.69 by diarrhœal diseases, and 192.48 by injury, of which 21.56 admissions per thousand men resulted from gunshot. Typhoid fever contributed only 20.69 cases per thousand of strength. In 1898 typhoid fever contributed 141.59 cases per thousand of strength. The deaths in 1899 amounted to 1,945, equal to a rate of 18.43 per thousand, as contrasted with 27.99 during the year 1898 and with 6.69, the mean of the preceding decade. The troops serving in Cuba had the highest rate of admission, 2,749.74 per thousand, as against 3,413.54 per thousand in 1898, the result of exposures during the active service of the Santiago campaign.

The statistics for the years 1898 and 1899 show that when the rates for the white and the colored troops of the whole army are compared, malarial infections occurred more frequently among the latter than among the former. This, however, does not imply a greater susceptibility on the part of the colored men, but is referable to the fact that during a part of the time all the colored regiments were exposed to Cuban malaria, while only a relatively small proportion of the large force of white troops was similarly exposed. In those instances in which white men and colored men were subjected to the same malarious influences, the white troops suffered more severely than the black soldiers. The health of that portion of the United States army, both of regular and of volunteer, serving in the Philippines during the time dealt with by the report, was fairly good. In 1899, with a mean strength of 39,280 regulars and volunteers, the admission rate for all causes of disability was 2,395.52 per thousand of strength; for disease, 2,206.36; for injury, 189.16; for gunshot injury, 52.26. The death rates corresponding to these admission rates were respectively 30.58, 15.28, and 12.60. It is satisfactory to note that although the admissions for disease, as well as the death rate from all causes, were considerably increased during the period referred to, the death rate from disease was appreciably reduced. The increased admission rate was due to diarrhœal diseases, malarial infections, and injuries. Diarrhœal diseases formed 642.80 and malarial infections 624.37 of the total admission rate.

The lessened rate of mortality from disease resulted from a lessened prevalence of typhoid fever, with a consequent lowering of the death rate from that disease. The lower death rate was also in part due to the milder character of the malarial infections, the death rate from these diseases being only 0.89, as compared with 1.51 in the preceding year. The increase in the totality of the death rate was the consequence of active service, as expressed by the mortality rate from gunshot, which was much higher than in the previous twelve months. Two hundred and sixty-seven cases of smallpox, 78 of which were fatal, gave rates respectively of 6.80 and 1.99 per thousand of strength.

The establishment of post and regimental hospitals is declared, as may well be believed, to have been of great benefit in relieving the base hospitals and those in Manila. Undoubtedly the most important work performed by army surgeons in the Philippines has been the care and attention given to sanitation, in which efforts they have been ably seconded by officers and men. Another point to which notice is rightly called is with regard to the food of the soldier in the tropics, and especially as to the criticisms that the regular ration contains too much meat and too little starch. Col. Charles R. Greenleaf, assistant surgeon-general, stationed in the Philippines, writes as follows upon the question:

"It has been alleged that the soldier should be fed somewhat after the manner of the native, largely on rice and starchy foods, and the quantity of his meat (beef and bacon) diminished. However sound these views may be as scientific theories, they are not supported by the results of practical experience. It does not appear after careful observation that the food furnished the soldier by the present ration produces sickness either by its variety, character, or quantity, provided it is properly cooked and eaten in moderation." In the MEDICAL RECORD, opinions almost identical with these have been expressed more than once. In Cuba the health of the troops, as was to a great extent to be expected, compared very favorably with that of the previous year.

This gratifying state of affairs was due not only to the fact that war, with its dangers to health and limb, was over, but also to the improvements in sanitation introduced and carried out by the energy of the army surgeons. In Porto Rico the death rate among the troops fell from 48.48 in 1898 to 11.27 in 1899, a sufficiently convincing proof of the altered conditions in that island. The report states that as regards smallpox the regular troops were better protected from the infection than the volunteers. This is shown by the relative prevalence of the disease among the troops in the Philippines in 1899, where large mixed commands operated during the whole year in a dangerously infected country. Among a mean strength of 22,922 regulars there occurred 110 cases, of which 28 proved fatal, while among the volunteers, with a mean strength of 16,358, there occurred 157 cases, 55 of which were fatal. The rate of admission per thousand of strength among the regulars was 4.80; among the volunteers 9.60; and while the death rate among the regulars was only one per thousand men, among the volunteers this rate was 3.36 per thousand. The coincidence is somewhat curious, as later in the report it is stated that although the number of vaccinated men is not known, probably all the accepted recruits for the regular army, together with the United States and State volunteers, were vaccinated or revaccinated in accordance with regulations. Mention is made of the appearance of bubonic plague in the Pacific Islands, and an interesting account is given of the history, epidemiology, bacteriology, treatment, and prevention of that scourge.

One of the most valuable papers contained in the report is contributed by Acting Assistant Surgeon Thomas W. Jackson, United States army, being the record of twelve months' observation of Cuban malarial fevers in Pinar del Rio Province. Pulmonary consumption as a cause of death in the army was practically the same in 1899 as in 1898. In the former year the admission rate for Porto Rico was 5.10, for Cuba 4.49, and for the Philippines 4.48; the highest death rates occurred in Porto Rico and the Philippines, 0.80 and 0.79 per thousand men. The admission rate for the army for venereal diseases exhibited in 1899 a rather deplorable increase. Alcoholism was responsible in the same year for a larger amount of sickness and mortality than in 1898, but official reports do not sustain the statements made by newspaper articles as to the disastrous effects of "vino" and other alcoholic drinks among our troops in the Philippines. During the year 1899 there were reported from the army, regulars and volunteers, 2,276 cases of gunshot injury, with 149 deaths, or 6.5 per cent., resulting from the wounds and 4 deaths from causes other than the wounds, 1,714 were returned to duty, 180 were discharged on certificates of disability, 134 by order and 80 by muster out or expiration of term of service. In 2,268 of the total number of injuries, the head, face, or neck was wounded in 257 cases, or 11.4 per cent.; the trunk in 402 cases, or 17.7 per cent.; the upper extremity in 763 cases, or 33.6 per cent., and the lower extremity in 846 cases, or 37.3 per cent. Of 98 wounds of the abdomen 38 were non-penetrating and 60 penetrating wounds. None of the former were fatal, but 41 of the latter proved fatal, constituting 68.3 per cent. of the whole number of penetrating wounds.

Insanity in the army in 1899 showed an increase over the mean annual rate of the decade 1888–97, but this higher rate has not been enough to warrant the sensational accounts which have appeared in the newspapers from time to time within the past year. The explanation given in the report, that this increase was to be anticipated on account of the rapidity with which recruiting was effected during 1898 and 1899, will satisfy those who are best qualified to pass a fair judgment on the matter. No one who reads the report of the surgeon-general of the army for 1899 with an unbiassed mind can do aught but give Dr. Sternberg and his coadjutors the highest praise for good work successfully accomplished. The manner also in which the result of and the experience gathered from their labors is set forth is most excellent. The report is greatly embellished by some really splendid photographs depicting hospitals in the Philippines which have been erected or converted to the purpose of caring for the sick, by the exertions of the army medical department.

CRUSADE AGAINST UNLICENSED MEDICAL PRACTITIONERS IN MINNESOTA.

THE State board of medical examiners of Minnesota is taking steps to prevent the illegal practice of medicine in that State. It appears that although the act to regulate the practice of medicine in the State of Minnesota is, with the exception of an amendment which was made in 1895, fairly stringent in its provisions, these are frequently broken or ignored. The

members of the board realize the fact that it is just as much their duty to punish persons violating the provisions of the act as it is to license physicians and surgeons, and, accordingly, action has been taken with this object in view. Since January 1, 1900, many prosecutions have been undertaken, all of which have proved successful. The medical board is now endeavoring to have the act revised, believing that the standard of medical education would be greatly advanced if this were done.

The policy of the board is set forth in a resolution passed January, 1900, as follows: "That from and after this date the secretary of this board be instructed to enforce the provisions of the medical act, and to require each and every person to obtain a license before beginning the practice of medicine in this State." It was further resolved at a meeting held in June, 1900, "That the secretary notify all physicians not residents of this State, who are known to be practising medicine in Minnesota other than as consultants, that it will be absolutely necessary for them to comply with the statutes, and the secretary be instructed to begin prosecution when necessary in such cases."

Not the least important duty will be the investigation of charges of dishonorable conduct on the part of certain advertising medical practitioners, which has been brought to the attention of the board.

This movement on the part of the Minnesota board is well advised and should be vigorously proceeded with. The MEDICAL RECORD has at all times advocated the raising of the standard of medical education in all the States and the prosecution of those who fail to fulfil the obligations placed upon them by the provisions of the medical acts. There seems to be at the present time an epidemic of quackery everywhere, and it is incumbent upon medical men to band together to protect their own interests. As pointed out in the MEDICAL RECORD, January 19th, it is the purpose of the Medical Society of the County of New York to begin an active crusade against unlicensed, and therefore incompetent, practitioners; and it will certainly be for the welfare of the medical profession throughout the United States if the examples of New York and Minnesota are followed.

THE SANITARY SUPERVISION OF CUBAN PORTS.

AMONG the propositions regarding Cuban relations, suggested as amendments to the Army Appropriation bill in Congress, is one "that the government of Cuba will execute, and as far as necessary extend, the plans already devised or other plans to be mutually agreed upon, for the sanitation of the cities of the island, to the end that a recurrence of epidemic and infectious diseases may be prevented, thereby assuring protection to the people and commerce of Cuba, as well as to the commerce of the southern ports of the United States and the people residing therein." This is a substitute for an amendment first proposed, that "the United States shall have sufficient supervision of the laws of Cuba relating to sanitation to protect this country from epidemics liable to originate in the island." We much prefer the wording of this proposition to that of the one to be adopted, for it offers greater security for the attainment of the object purposed. When the revolution in Cuba began six years ago, we called attention to the possible effect of its success upon the health of this country, in that the opportunity would be open to us to clean out the pest holes which Spanish misgovernment had created and maintained there. Now that we have had sanitary control of the island for two years, and that the labors of General Wood, Major Gorgas, and others have accomplished so much, we cannot afford to endanger the results already obtained by unconditionally turning affairs over to inexperienced hands. There are men of the highest scientific attainments in Havana and elsewhere in Cuba who, if permitted, would continue the good work initiated by medical officers of the U. S. army and Marine-Hospital service. It is for this country to see to it that these competent men are not thrust aside, the control of sanitary matters being given to ignorant laymen as a reward for political services. That the fear of such action is not an idle one is shown by the protest of a Cuban paper recently against the expenditure of so much money on sanitation, the ground for the editor's objection to cleanliness being that the natives were immune against yellow fever; and the non-immune foreigners could stay away or die as they preferred. The stamping out of yellow fever in Cuba is a matter of vital importance to us, and the United States should have a controlling voice in sanitary affairs on the island, at least until this object has been accomplished.

News of the Week.

The Medical Society of the Missouri Valley will hold its annual meeting in Omaha, March 21st.

Scarlet Fever and Yale Students.—Two cases of scarlet fever have been discovered in a Yale University boarding-house.

Academy of Medicine.—In the section on general medicine, Dr. E. Franklin Smith has been elected *Chairman* and Dr. James N. West *Secretary*.

Religious Services to Smallpox Patients by Telephone.—In Mount Pleasant, Mich., where smallpox prevails, a large number of victims received simultaneous religious consolation by telephone.

Fined for Falsifying a Death Certificate.—A Brooklyn physician has been fined $100 in the Court of Special Sessions for having filed a false death certificate in the case of a man who died of smallpox. A cause of death other than the true one was given in the certificate.

Annual Dinner of Mount Sinai Hospital Alumni Association.—The annual dinner of this association was held February 20th, at the Arena. Dr. Charles H. May, the president, acted as toast master, and the following guests responded to the toasts: Dr. George

F. Shrady, Dr. E. Gruening, Mr. Wallach, president of the board of trustees of the hospital, Dr. A. Jacobi, Dr. John A. Wyeth, Dr. Mark Blumenthal, and Dr. B. Sachs.

A Hospital Quarrel in Orange.—The house physicians at the Orange (N. J.) Memorial Hospital recently sent in their resignations to the medical board, with a request for their immediate acceptance. This action is said to be the outcome of a quarrel with the woman superintendent.

Burning of a Hospital in Tokio.—The hospital of the medical department of the University of Tokio, Japan, a wooden structure, was totally destroyed by fire on January 29th. Twenty-one of the patients were burned to death, and ten patients and nurses were more or less seriously injured.

The Loss of the "Rio de Janeiro."—By the sinking of the Pacific Mail steamship at the entrance to San Francisco harbor, two physicians were drowned, Dr. William E. Dodd, an ophthalmologist of Butte, Mont., and Dr. Onkawara, a Japanese physician. Dr. Arthur O'Neil, the ship's surgeon, was saved.

The California Medical Practice Bill, now before the legislature of that State, is in danger of being beaten by the osteopaths, Christian scientists, and quacks of all sorts and conditions. There are said to be twenty-seven Solons pledged to vote against it, and the papers state that Governor Gage, never conspicuous for his devotion to science, has joined the forces opposing it, and promises to veto the measure if he cannot prevent its passage in the legislature.

The Plague at Cape Town.—An exacerbation of the plague which has been lurking in a number of coast towns in South Africa for many months, recently occurred at Cape Town and caused some uneasiness lest the British troops stationed there should be attacked. The visitation is reported now to be subsiding, and no new cases have appeared among the eighty Kaffirs who were under detention after having been exposed to contagion. The mortality has been light and no cases have appeared among the British troops.

Hazing a Medical Student.—A student in the medical school of the University of Maryland, Baltimore, whose mustache had been cut off by some of his fellow-students in an upper class, caused the arrest and fining of his tormentors. Feeling ran high against him, and in order to give it time to subside he remained away from the lectures for a week or ten days. His stay was not long enough, however; for on putting in an appearance in the lecture room he was greeted with hisses and groans and pelted with rotten eggs, while a large portion of the class left the lecture as a protest against his presence.

Smallpox is still prevalent in this city, despite the efforts of the health officials to subdue it, one or two new cases being reported almost daily. There has been a great falling off in the number of vaccinations during a few weeks past, the alarm of the public caused by the discovery of the first few cases having been succeeded by apathy. The health board recently appealed through the newspapers to the people of the city to protect themselves by vaccination, otherwise, it was intimated, a serious outbreak was to be feared. This apathy is in contrast with the active interest aroused in Woodbury, N. J., by the discovery of three cases there last week. The health officers ordered all the churches, Sunday schools, day schools, and the public library closed, and citizens were warned not to congregate in crowds. Within a few days after the discovery of the first case, over four thousand vaccinations were made.

The President of Johns Hopkins Resigns.—Dr. Daniel Coit Gilman, president of the Johns Hopkins University, Baltimore, has resigned, the resignation to go into effect at the close of the academic year, September 1st. Dr. Gilman has been with the university since its foundation, twenty-five years ago.

Suicide of a Hospital Patient.—A patient in a ward on the fourth floor of the Columbus Hospital got rid of the attending nurse one morning, and running to the window, flung himself headlong out. He struck on the roof of a one-story extension, and died in a few minutes. He was under treatment for Bright's disease.

Spitting in Street Cars.—The Metropolitan Street Railway Company is causing to be placed in its cars a revised anti-spitting notice, which specifies that spitting upon the floor of a car is a violation of the sanitary code, and is a misdemeanor, the extreme punishment for which may be $500 fine and one year's imprisonment, or both. The warning is very salutary, the law of the matter is good, and we hope that violators will be made an example of.

Christian Science and Testamentary Ability.—The will contest which has been going on in this city for several weeks has reached the stage of calling medical experts to testify as to whether or not a person who accepts entirely the tenets of so-called Christian science is of a mind sufficiently sound to dispose of her estate without the intervention of the law. The weight of the medical evidence has been that a person who believes in Christian science is suffering from a delusion and is consequently not sane in the strict meaning of the word. Many absurd statements have been elicited from the Christian science witnesses called to support the will. One treated a wilting rubber plant successfully by "absent treatment." The recovery of the rubber plant may have been in part due to the fact that some one else began to try hydrotherapy when the wilting was observed, as was also testified in this interesting trial.

Discussion on the Social Evil at the Academy of Medicine.—Dr. Prince A. Morrow read on Monday evening, February 25th, at the Academy of Medicine, a paper on the medical aspects of the social evil. In the course of his remarks he said "that the attempt to regulate vice in the cities of Europe by a system of fees and licenses had not been successful." William H. Baldwin, Jr., chairman of the committee of fifteen.

said "that the idea of uprooting the evil altogether was Utopian; for himself he preferred a little of hell with certain restrictions to a great deal of hell." Dr. Frederick R. Sturgis advocated the licensing and regulating of the social evil and contended that the experiment had been successful in St. Louis. Finally, the members of the academy voted to investigate the social evil in this city, and authorized their president, Dr. George B. Fowler, to appoint a committee of seven to do it.

A Suit to Test the Vaccination Law has been brought in Chicago by a man whose unvaccinated children have been excluded from the public schools. The complainant contends that his children are free from contagious disease, and refuses to have them vaccinated, on the assumption that the virus has frequently caused sickness and death.

The Hospital Ball in Aid of St. John's Guild and the Red Cross Hospital.—This ball was held at the Metropolitan Opera House on Tuesday night, February 12th, and was a brilliant success. Edward Strauss, brother of the celebrated Viennese composer known as the "Waltz King," conducted the music. Several diplomatic representatives of foreign nations were present, some in court costume, and the army and navy were well represented.

A Medical Student's Good Work.—In the railway accident near Camden, N. J., last week, in which many lives were lost and a number of persons were injured, no physician was found on either train. A medical student of the class of 1902 in the University of Pennsylvania (the papers did not give his name), who happened to be present, did very effective work in the care for the injured, washing and bandaging their wounds and giving first-aid instruction to those able to assist in the work.

A New President of the Board of Health.—Mayor Van Wyck has appointed Mr. M. C. Murphy, former president of the health board of this city, police commissioner, and put in his stead as president of the health board one of the former police commissioners, a Mr. Sexton. The new incumbent of this most important office is forty-four years old, and has been from early youth a professional politician. He was an under sheriff for nine years, sheriff for two years, and police commissioner for three years. His qualifications for health commissioner are not apparent, but probably the work of the board will not be seriously affected if no emergency requiring a knowledge of sanitary matters arises. His salary is $7,500 a year.

A Course of Clinical Lectures on Syphilis will be given at the New York Skin and Cancer Hospital on Wednesday of each week, beginning on March 6th, and ending May 1st. The course is free to physicians. The following is the programme of the lectures to be given: March 6th, "Syphilis as a Disease: Modes of Infection: Extra-Genital Syphilis," by Dr. L. Duncan Bulkley; March 13th, "Skin Manifestations of Syphilis," by Dr. L. Duncan Bulkley; March 20th, "Infantile Syphilis," by Dr. A. Jacobi; March 27th, "Syphilis of the Mouth, Nose, Throat, and Larynx," by Dr. D. Bryson Delavan; April 3d, "Syphilis of the Eye and Ear," by Dr. David Webster; April 10th, "Syphilis of the Nervous System," by Dr. Edward D. Fisher; April 17th, "Syphilis of Internal Organs," by Dr. Edward G. Janeway; April 24th, "Syphilis of the Bones, and Surgical Relations of Syphilis," by Dr. Willy Meyer; May 1st, "Synopsis, Conclusions, and Treatment of Syphilis," by Dr. L. Duncan Bulkley.

Epidemic Grippe.—During the past month grippe has prevailed in epidemic form throughout Connecticut, Illinois, Indiana, Maryland, Massachusetts, New Hampshire, New York, Ohio, Pennsylvania, South Carolina, Wisconsin, and Virginia. The disease has been of catarrhal type and with a low rate of mortality.

Smallpox in Glasgow.—The outbreak of smallpox in Glasgow has been kept well in hand, and the sanitary officers have found ready co-operation from the inhabitants of the city. Nevertheless the number of patients is large, amounting to four hundred and thirty-three patients in hospital.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ending February 23, 1901. Assistant Surgeon R. C. Holcombe detached from the *Glacier* and to duty with marines at Pollok, P. I. Special orders, February 15, 1901.—Department of Cuba directs Surgeon J. W. Ross, retired (United States navy), to report to the chief sanitary officer, city of Havana, for duty.

Hearing on Anti-Clairvoyant Bill.—On February 21st, the senate committee on cities gave a hearing on Senator Wagner's bill making it a misdemeanor to practise clairvoyancy, palmistry, or fortune telling. Henry Richardson, who represented the clairvoyants on the Christian Science bill hearing before the assembly committee last week, again appeared for them, and by his reasoning seems to have succeeded in convincing the committee that the legislature had no right to interfere.

The New York Academy of Medicine.—The order of the stated meeting of the New York Academy of Medicine for March 7, 1901, is as follows: "Discussion on Alcohol and Alcoholism," by Prof. R. T. Chittenden, of Yale University, and "A Discussion of Alcohol as a Food; its Direct Action on the Nerve Cell; its Effects on Americans, and the Aspect of the Law and the Inebriate," by Drs. A. A. Smith, M. Allen Starr, H. M. Biggs, Walter B. James, J. Ewing. Joseph Collins, and others.

The Amended Medical Bill.—The assembly public health committee will report for amendment and recommitment Assemblyman Bell's anti-Christian Science bill this week. The bill will be amended so as to affect only faith-cure people and make all persons who pretend to be healers and cure the sick and injured pass an examination before the State board of regents, showing their competency in caring for the sick, and

their knowledge of disease by requiring a knowledge of practical diagnosis. Dr. M. H. Henry, the chairman of the committee, finds that the bill has stirred up more dissension in the medical fraternity than any other kind of legislation ever proposed.

Obituary Notes. — Dr. Pierce B. Fagin, aged eighty-two years, a pioneer of California, is dead at Santa Cruz. Dr. Fagin laid out the site of the city of Des Moines, Iowa, in 1846. He was a native of Iowa, and was graduated in medicine in 1876.

Dr. I. Newton Jones, of Cincinnati, died at his home in that city on February 21st, of pneumonia. He was a graduate of the Medical College of Ohio, in the class of 1866.

Dr. Thomas O'Reilly, one of the oldest physicians in St. Louis, died at his home in that city on Sunday last, of influenza. He was born in County Cavan, Ireland, seventy-four years ago, and was licensed by the Royal College of Surgeons, London, in 1849. In that year he went to St. Louis, and had practised there ever since. He was a prominent member of many Irish societies, and was a notable home-rule advocate.

Dr. Samuel Camp, of Great Barrington, Mass., died on February 24th at his home, aged seventy-two years. He was born in Winsted, Conn., and was graduated in 1851 from the Medical Department of the University of New York. He began to practise medicine, immediately after his graduation, in New Marlborough, Mass. Four years later he went to Michigan, returning in 1859 to Great Barrington, where he lived until his death. He served in the civil war as surgeon of the twenty-seventh Massachusetts regiment.

Dr. E. E. Pirrie, an Edinburgh graduate, formerly of Louisville, Ky., was killed some months ago in South Africa, where he had been serving as assistant surgeon in the Gordon Highlanders. In this capacity he had gone upon the field after a battle with a squad of hospital orderlies to look after the wounded. The party displayed the Red Cross, but the Boers fired upon them. The first volley wounded a litter bearer. Dr. Pirrie was attempting to indicate to the enemy that his men were non-combatants, when a bullet struck him in the breast and killed him almost instantly.

Dr. Mayo G. Smith died February 23d at Colorado Springs, Col. He was born in Newburyport, Mass., in 1816. He was one of the first graduates of Oberlin College, and was an intimate friend of Horace Greeley. Dr. Smith was the author of two works on ether and chloroform based on experiments he had conducted, and was associated with Morse in completing the telegraph and constructing the first line between Washington and Baltimore.

Dr. S. A. Mercer Given, proprietor of the Burn Brae Sanitarium at Clifton, Delaware County, Pa., died on February 23d, at the age of forty-one years, from diabetes.

Dr. William H. Egle died of pneumonia at Harrisburg, Pa., on February 19th, at the age of seventy-one years. He was graduated from the medical department of the University of Pennsylvania in 1859, and in 1862 became surgeon to the ninety-sixth Pennsylvania volunteers. He was one of the pension examiners and for twenty years prison physician. In early life he was a newspaper editor, and from 1887 to 1899 State librarian. He was for thirty years a surgeon in the national guard, retiring a year ago as surgeon-in-chief of the third brigade. He was the author of a "History of Pennsylvania," and he edited the Pennsylvania archives.

Dr. Bawater J. Vernon, F.R.C.S., England, a very well-known London surgeon and eye specialist, died very suddenly of heart disease on January 28th. The deceased gentleman had been attached to St. Bartholomew's Hospital for a number of years.

Dr. Abbott Hodgman, of this city, died February 26th, aged sixty-five years. He was graduated from the New York University Medical College. He was a trustee of the Metropolitan Museum of Art and a member of the New England Society.

Progress of Medical Science.

New York Medical Journal, February 23, 1901.

The Relation of Scurvy to Recent Methods of Artificial Feeding.—By J. P. Crozer Griffith. The author finds an etiological factor in the extensive use of proprietary foods, in food containing or derived from starch, and, occasionally, in the use of cooked or partially cooked milk. It is difficult to speak positively concerning the last named, for we so often find proprietary foods used in connection with milk that it is difficult to estimate the relative weight of each of these two factors. In sterilized milk the trouble may lie not in the milk itself, but in the absence of the proper proportions of proteids, fats, and sugars. A series of sixteen cases is given illustrative of the general statements above made. The great remedy in the disease is fruit juice. When this is added to a given diet, it is often possible to continue the latter without modification. Every case must be a law unto itself as concerns dietetic management, for what is one baby's meat is another baby's poison.

A Simple and Accurate Method of Substitute Infant Feeding.—By H. D. Chapin.

The Pathology of Intra-Uterine Death.—Continued article by N. McPhatter.

The Normal Declinations of the Retinal Meridians.—By G. T. Stevens.

State Care of the Insane.—By H. W. Coe.

Medical News, February 23, 1901.

Pharyngeal Adenoids and Hypertrophied Tonsils.—J. H. Woodward states that the excitation of aural disease is the chief mischief attributable to the existence of pharyngeal adenoids. Deafness may occur as the result of direct occlusion of the orifices of the Eustachian tubes by this growth—without inflammation of the tympanum. The deleterious influence of adenoids upon the patient's general health is most important. The symptomatology of pharyngeal adenoids may be thus considered: (1) Symptoms common to all cases of adenoids. (2) Symptoms dependent upon the size of the adenoids. (3) Occasional accessory symptoms. Under the first group are: (*a*) hyperplasia of the lymphoid tissue in the vault of the pharynx; (*b*) chronic congestion of the submucous blood-vessels of the inferior turbinated body; (*c*) a more or less profuse mucopurulent discharge. Under the second group are: (*a*) alteration of the voice, as if the patient were suffering from a cold in the head; (*b*) mouth-breathing; (*c*) snoring and choking in sleep; (*d*) general malnutrition; (*e*) deafness; (*f*) chronic headache and mental dulness. The third group comprises: (*a*) asthmatic seizures; (*b*) habit (facial) chorea; (*c*) epileptiform attacks. The symptoms attributed to hypertrophied faucial tonsils are: (*a*) alteration of the voice—giving a muffled quality; (*b*) snoring and choking in sleep; (*c*) excessive secretion of mucus in the throat; (*d*) frequent attacks of acute catarrhal inflammation in the throat, and follicular tonsillitis; (*e*) chronic enlargement of the cervical lymphatic glands; (*f*) mouth-breathing; (*g*) deafness; (*h*) general malnutrition. The writer states that the alleged evil effects of tonsillotomy upon the organs of generation have not come under his observation. He has not encountered a patient on whom tonsillotomy had been done, who was not benefited in some measure at least by the operation.

The Sustaining Treatment of Typhoid Fever with Special Reference to the Use of Hypnotics.—A. H. Buckmaster concludes that: No practitioner has done his duty, who does not know at the end of each twenty-four hours that the patient has had enough food, water, and fresh air; who has allowed the patient to wear himself out by continued high temperature or by lack of sleep (the amount of sleep in the twenty-four hours should be recorded); who has not posted himself daily as to the condition of the urine, the movements of the bowels, and the condition of the skin.

A Report of Some Cases of Abdominal Surgery, with Remarks on the Diagnosis of Carcinoma of the Cæcum and the Surgical Treatment of Carcinoma of the Liver and the Gall Bladder.—By Charles Greene Cumston.

The Value and Accuracy of the Roentgen Method of Diagnosis in Cases of Fracture.—By Charles Lester Leonard.

Nasal Obstruction; Mouth-Breathing; Catarrh; Dilators.—By Norburne B. Jenkins.

Compound Dislocation of the Knee.—By Walter Lathrop.

Journal of the American Medical Ass'n, Feb. 23, 1901.

The Importance of an Early Diagnosis of Tuberculosis.—A. Mansfield Holmes states that when the vital forces become impaired from any cause whatever, the resistance to tuberculous infection is diminished and the danger of infection increased. When the germs are brought in contact with the weakened tissues, the actual beginning of tuberculosis is instituted. Early diagnosis is of supreme importance. There are early symptoms which appear long before the stage of expectoration; and the latter is present very often for a considerable time before bacilli can be found. When early symptoms are present and no other cause can be found to account for them, we are justified in suspecting tuberculosis. The previous history, general appearance, and symptoms should be well considered before a diagnosis is made. Repeated physical examinations, bacterial examinations of the sputum, and microscopical examinations of the blood should be made. If any doubt then exists, a tuberculin test should be tried. Hygienic means should be employed most carefully by both patient and physician, and when greater care is taken to recognize the early symptoms and then to prevent infection, fewer cases may be expected.

The Bacterial Toxins.—Victor C. Vaughn and Thomas B. Cooley believe that the colon bacillus in virulent form contains within the cell a toxin which is fatal to guinea-pigs of from 200 to 300 gm. weight, in quantities of less than 1 mgm. The aqueous extract of the cells of the colon bacillus grown on agar is inert. The entire germ is highly resistant to heat and to dilute acids and alkalies. The cell wall of the colon bacillus is digested by the prolonged action of artificial gastric juice, which does not alter the toxin. The toxin as thus obtained is insoluble, or but slightly soluble, in dilute acid, but is slightly soluble in water and more readily in dilute alkalies. This toxin responds to the ordinary proteid reactions. The toxin, after being freed from the cell membrane, is not destroyed by being boiled.

Some Observations in Mastoid Operations.—A. W. Calhoun concludes that there is infrequency of mastoid disease as compared with the large number of cases of suppurative otitis media. The disease is of mild type, having a marked freedom from cerebral and other dangerous complications. The negro race is comparatively exempt. Serious mastoid disease is sometimes present without marked outward symptoms. There are cases without apparent middle-ear involvement. Not every case requires radical operation.

Anastomosis of the Ureters with the Intestine; a Historical and Experimental Research.—By Reuben Peterson.

The True Role of Drugs in the Management of Consumptives.—By Solomon Solis-Cohen.

Differential Diagnosis between Chickenpox and Smallpox.—By Herman Spalding.

Suppurative Tympano-Mastoiditis in Children.—By Herman Knapp.

Philadelphia Medical Journal, February 23, 1901.

Resection of the Rectum per Vaginam.—John B. Murphy believes that the following advantages are offered by the vaginal route: (1) The sacrum and posterior bony wall of the pelvis are not disturbed. (2) The field of operation is as extensive and the anatomical parts as accessible as in the transsacral operations. (3) The peritoneal cavity is opened in both the vaginal and sacral operations, and in neither is it a source of great danger. (4) The diseased tissue is more accessible for inspection and the extent to which the operation may be carried in an upward direction is as great, if not greater than by the sacral route. (5) The peritoneum may be drained freely through the vagina. (6) A perfect end-to-end approximation, either by suture or by the use of the button, may be secured. The preferable method of uniting the two ends is by interrupted sutures of silk, because, as there is no peritoneum on the sphincteric segment, failure of union with the button is to be feared. (7) The sphincter is retained and the perineal body is restored. There is diminished action of the levator ani muscle. (8) When the operation is complete, the parts are practically in their normal positions.

The Value of Sputum Examinations to the General Practitioner.—M. Howard Fussell speaks of the necessity and value of these examinations. A detection of the organism of tuberculosis in the very early stages would be of incalculable value to the human race. In the large cities the board of health will examine the sputum at short notice, free of charge. The whole process of staining for the bacilli will not take more than fifteen or twenty minutes.

Congenital Umbilical Hernia; Report of a Case, and Table of Cases Hitherto Reported.—By Homer E. Safford.

Amputation of Both Feet Under Spinal Anæsthesia with Cocaine.—By Augustus C. Behle.

Sarcoma of the Ribs.—By C. C. Warden.

Boston Medical and Surgical Journal, Feb. 21, 1901.

Dysenteric Diseases of the Philippine Islands with Special Reference to the Amœba Coli as a Causative Agent in Tropical Dysentery.—Joseph J. Curry says that the amœbic type of dysentery occurred in over sixty-six per cent. of the cases of dysentery which came to autopsy. This is the most common type of dysentery found all over the islands. The fact of the amœbæ occurring so frequently as they do in the liver abscess contents found in the course of tropical dysentery; the absence of bacteria from these abscesses generally; the rarity of abscesses of the liver in the course of dysenteries other than those in which amœbæ are present, and the general constant characteristic pathological picture at post-mortem, all weigh strongly in favor of the amœba coli as the principal causative agent in one type of tropical dysentery. An acute type of dysentery has been observed in the Philippines in which the bacillus dysenteriæ of Shiga occurred. In addition, cases of subacute and chronic dysentery have been met, in which neither the amœba coli nor the bacillus dysenteriæ was found.

Uterine Fibroids.—Homer Gage considers severe and exhausting hemorrhages, and rapidity of growth of tumors, as well as persistent pain, interference with the functions of the bladder or rectum, and ureteral obstruction, indications for operation. Operation is also worthy of consideration when the mere knowledge of the existence of the tumor induces a condition of chronic invalidism. Age should be a small factor in determining the question. Not only do fibroids tend to delay and prolong the menopause, but in a study of four hundred cases Kattmann found that in nearly twenty-five per cent. neither climacteric nor menopause had any hindering effect on their growth. As to the choice of operation the author uses dilatation and curettage whenever possible. He has performed radical operations in many cases. Myomectomy he has done only six times, but with very gratifying results, and he believes that a steady improvement in technique will widen the field for the practice of this measure, giving us, at least in a very large number of cases, a safe, non-mutilating method of dealing with uterine fibroids.

Dysbasia Intermittens Angiosclerotica; Intermittent Lameness of Vascular Origin.—James J. Putnam reports a case of this very rare affection which is characterized by the sudden and intermittent appearance of a helpless, cramp-like feeling in the legs, which checks motion. The theory held is that the condition is due to a limitation of the arterial supply to the muscles. The author questions the accuracy of this theory, for a careful examination of his patient's arterial circulation in the feet showed that one of the posterior tibial arteries could be felt distinctly, the other faintly, while the dorsal arteries could not be recognized. The same conditions obtain since the patient's improvement. A vascular spasm is perhaps the best explanation.

United States Army Pathological Laboratories in the Philippine Islands.—Joseph J. Curry gives an account of the work done in the three laboratories in and near Manila. Two of these were on hospital ships, and the author says that, in smooth water and at anchor, it is possible to do practically the same work in them as in a laboratory on land. Not only is it valuable to be able to establish a diagnosis on shipboard, but the hospital ship, moving as it does to the various ports in the islands, can render the service of a portable laboratory to the cities and the towns which the ship reaches. Excellent work has been done in the investigation of the bubonic plague, and of other diseases as well.

Clinical Meeting of the Medical Board of the Massachusetts General Hospital.—"Rupture of the Right Iliac Artery," by F. C. Shattuck; "Lead Encephalopathy," by F. C. Shattuck; "Osteo-Arthritis," by F. C. Shattuck; "Friedreich's Ataxia," by James J. Putnam; "Splenectomy," by I. C. Warren; "Loose Semilunar Cartilages," by I. C. Warren; "Plastic Operations for Rodent Ulcer," by I. C. Warren.

British Medical Journal, February 9 and 16, 1901.

A Clinical Lecture on a Case of Chronic Cancer of the Face.—F. T. Paul reports a case of cancer of the sweat glands. He states that rodent ulcer is a carcinoma of one of the appendages of the skin, and differs from epithelioma, which is a carcinoma of the rete mucosum. It is probable that cancer of the sweat glands differs as much from cancer of the sebaceous glands as the latter does from cancer of the rete. This case, while it possesses some of the clinical features of cases of cancer of the sebaceous glands, or ordinary rodent ulcer, tends to grow into a solid tumor instead of excavating the face, as would happen when the characteristic erosion of the latter occurred. The writer believes that there are two kinds of carcinoma of the skin appendages, both of which are characterized by continuous slow growth; but in only one, true rodent ulcer or carcinoma of the sebaceous glands, does ulceration keep pace with growth. The two varieties of adenoma of the skin glands are fairly well recognized. In the case reported, the disease has been continuously present in the patient for many years without treatment or interruption of any sort, and is still slowly progressing without secondary infection; consequently it cannot be epithelioma. Microscopical examination also proves the structure to be that of a glandular type of growth. As to treatment of rodent ulcer, the examination should be microscopically thorough and uncompromising, and complete and immediate removal of the growth should be accomplished.

Remarks on the Heart-Index Interval in Aortic Regurgitation.—Paul M. Chapman states that the pulse wave produced in cases of aortic regurgitation is slow. This he takes to be the main phenomenon in pulse delay. When delay is observed in these cases, increased arterial tension tends to obliterate the delay. Diminished arterial tension makes it still more manifest. In a hypertrophied heart, the large mass of muscle would, for physiological reasons, contract more slowly, owing to the propagation of nervous impulse through its substance being more slow. To this, in all probability, is due the slight increase in the duration of ventricular systole (a rare phenomenon), showing that the ventricular contraction is actually a slow contraction, the duration of ventricular contraction being strangely independent of extraneous conditions. If it is considered, however, that as compensation is attained the arteries are better filled, giving to the patient a corresponding sense of comfort, and that then the pulse wave is accelerated, it will be seen that the attainment of a normal heart-radial delay is some measure of the correctness of the compensation, and that this may be a guide to avoid further interference.

A Preliminary Communication on the Treatment of Rodent Ulcer by the X-Rays.—James H. Sequeira, having a severe case of rodent ulcer referred to him for the Finsen treatment, and finding that the patient was unable to bear the pressure of the special apparatus which is used in the Finsen method to render the parts under treatment anæmic, applied the x-rays. Improvement resulted in this case as well as in others in which this treatment has been used. So far, the writer has treated only cases which have been deemed unsuitable for operation, or in which patients have refused operative measures. Of the twelve cases of the writer, eight are still under treatment and four are under observation, the ulcers having healed. Stenbeck, of Stockholm, records the successful treatment of a case of rodent ulcer by an almost identical method. His case is the first in which this procedure was adopted. In no instance in the writer's cases has there been a disappointing result. The treatment is painless and nothing further is required than covering the part with a simple antiseptic dressing.

Cerebellar Abscess Successfully Treated by Operation.—Thomas Barr and James H. Nicoll report a case of this kind and draw the following conclusions from their experience: (1) Early operative interference in the way of discovering and subsequently draining the cavity offers the only chance of recovery in cases of intracranial pyogenic lesions; (2) the results in such cases of operative interference have been much more favorable in temporosphenoidal than in cerebellar abscess; (3) the cause of death in cerebellar abscess is, in a large majority of cases, dropsical distention of the lateral ventricles (with œdema of the surrounding brain tissue). This ventricular dropsy appears to be the result of obstruction of the veins of Galen, produced by thrombosis originating in their lumina, or extending thence either from the superior cerebellar veins or from the straight sinus.

The Electrolytic Deposit of Sulphur from the Harrogate Sulphur Waters as a Therapeutic Agent.—Francis William Smith, from his experiments with the Harrogate sulphur water, believes that the nascent sulphur is deposited by electricity at the positive pole; that the same occurrence takes place on the skin of patients in a sulphur bath under similar circumstances; that in addition to the remedial influence of nascent sulphur, electricity stimulates the peripheral nerves all over the body in a sulphur bath, and thus renders the action of sulphur more rapid and more efficacious in skin and gouty affections.

Facial Neuralgia Due to a Hair Irritating the Membrana Tympani.—A. Percy Allan reports the case of a man aged twenty-one years, who had suffered from acute paroxysmal neuralgia for three months. Having excluded dental and ocular causes, the ear on the affected side was examined, and the membrana tympani was seen to be much injected. By means of the auriscope a hair was discovered lying along the meatus, and was pressing with its end on the tympanic membrane. It was removed, and the patient immediately experienced relief. After a day or two the attacks of pain entirely ceased.

An Address on the Need of Bacteriological and Pathological Laboratories in Dublin.—Sir George Duffey refers to the need of establishing in Dublin an institute similar to that of the Jenner Institute of Preventive Medicine of London. He states that it is to the study of bacteriology in relation to medicine, pathology, and to hygiene that we must look for more light in the treatment of disease and in our efforts for its prevention. He also advocates the establishment of a pathological laboratory for Irish asylums, to promote the study of the pathology of mental diseases.

The Surgery of Pregnancy and Labor Complicated with Tumors.—Lecture by J. Bland-Sutton. When an ovarian tumor occupies the pelvis and offers a mechanical impediment to delivery, the fœtus almost invariably dies, and the following accidents may happen: (1) Rupture of the cyst, (2) rupture of the uterus, (3) rupture of the vagina, and (4) extrusion of the tumor into the rectum. Rupture of the cyst is the way in which nature usually overcomes the difficulty. The choice of treatment really lies between two methods: (1) In the early stage to push the tumor out of the pelvis and allow labor to be completed and then at some convenient season to perform ovariotomy. This is often referred to as "reposition." (2) To perform ovariotomy at once and then to accelerate the labor by the use of forceps. If the tumor cannot be extracted, then Cæsarean section should be performed. This method may be conveniently referred to as ovariotomy which may occasionally require Cæsarean section.—Second of three lectures by J. Bland-Sutton. The present lecture covers the subjects of uterine fibroids and ovarian tumors. The general conclusions are that the ovarian growths give more trouble to pregnant and parturient women than do fibroids, but that the latter are far more lethal, as they so frequently destroy puerperal women from sepsis. Several clinical histories with illustrations are given, as well as two statistical tables. The author says that the facts at our disposal indicate very certainly that uterine fibroids, even more than ovarian cysts, are a grave menace to successful pregnancy, and in a large number of cases are directly responsible for a premature termination of the pregnancy. When abortion happens the patient requires to be safeguarded most strictly against infection, for it may involve the fibroid, and in this event the patient not only runs a very great risk of losing her life, but she certainly will have a long illness, and in many instances a serious operation may be necessary to prevent her from becoming a chronic invalid. We must not forget that a woman may have one, and, indeed, several fibroids in her uterus, and yet be the happy and healthy mother of children, but no one will deny that the presence of a fibroid in a gravid uterus is an additional peril to those which are proverbially associated with pregnancy. It occasionally happens that a woman comes under observation, known to be suffering from a combination of pregnancy and fibroids, and a careful examination discloses the fact that, if the pregnancy goes to term, delivery by the natural passages would be impossible. In these circumstances hysterectomy is justifiable.

Primary Sarcoma of the Stomach.—By W. S. Fenwick. Fenwick believes that the studies of recent years justify the conclusion that many of the growths of the stomach, commonly regarded as carcinomata, are really sarcomata. This opinion is founded partly on the discovery that many specimens which are described in museum catalogues as examples of carcinomatous or fibroid tumors, present the microscopical characteristics of round-celled or spindle-celled sarcoma, and partly upon the large number of cases of sarcoma of the stomach which have been published since special attention has been drawn to the subject. The most common type is the round-celled growth, though the spindle-celled, the myo- and angio- varieties have been met with. Like carcinoma, the process is apt to attack old scar tissue in the stomach. Differential diagnosis may be difficult, for some cases of sarcoma give no symptoms whatever. We may be guided in our judgment by the following facts: (1) The disease usually occurs before thirty-five years of age, so that the younger the patient the greater the probability that the malignant affection is sarcomatous in character. (2) In many cases there is slight but continuous pyrexia accompanied by rapid and profound anæmia, while in carcinoma fever is always absent during the early stages of the complaint and the cachexia much more gradual in its development. (3) Simple enlargement of the spleen is by no means infrequent, but is never met with in cancer unless the organ is involved in the growth. (4) According to Kundrat the tonsils are apt to enlarge and the follicles upon the sides of the tongue may become swollen or ulcerated. (5) Secondary deposits in the skin occur in a notable proportion of the cases, and permit of excision and microscopical examination. It should be remembered, however, that sarcomatosis has been met with in true cancer of the stomach. (6) A large nodular tumor due to infiltration of the omentum or a greatly enlarged liver with secondary growths in its substance are rarely met with. (7) Persistent albuminuria is often observed in sarcoma but is exceptional in cancer. (8) The discovery of pieces of morbid growth in the vomit renders the diagnosis certain.

Considerations Touching the Pathology and Relations of Diabetes.—Second Baillie lecture by W. H. Dickinson. The special topic of the lecture is glycogenesis. Concerning diet the author says that a proper diet will lessen the diabetic perversion, though it does not always abolish it. The substitutes for ordinary bread present the chief difficulty. Gluten bread is theoretically correct, but some patients cannot get it down; they say it is like chewing india-rubber. But the gluten flour need not be made into bread, and it is often less objected to in other shapes which can be given to it in the domestic kitchen, in cakes, buns, and puddings. Bran biscuits often do well and are useful, as they tend to obviate the constipation which is one of the troubles of the disease. Green vegetables—spinach, French beans, and the like—are fully recognized as fit for the diabetic; but mention may be made of some vegetable products which are not green and yet are of especial use in diabetes; namely, vegetables containing much cellulose. It is true that cellulose is a carbohydrate, but it does not appear to be easily converted into sugar, and indeed it is doubtful whether in the human body it undergoes any such conversion. One of the troubles of diabetes is constipation; cellulose largely passes off in the fæces and tends to obviate this condition. The more bulky varieties of garden stuff, whether roots or fruits, may be made use of, such as cucumbers, vegetable marrows, tomatoes, and radishes. Apples, if not obviously sweet, may be permitted in small quantity. These articles of diet are not all absolutely free from sugar, but none contain much sugar, and certainly they are often useful, though perhaps not absolutely correct in theory. Anything is better than nothing, and if the diabetic cannot take what he should he had better take what he can.

Why Are Both Legs of the Same Length?—By G. E. Wherry. As a fact, says the author, our lower limbs are not usually both of exactly the same length, though they are so for all practical purposes. The left is usually the longer, though the gait is not notably influenced by this fact. At birth the lower limbs are shorter than the upper, and their movements are rather of the prehensile type. "We are not born leggy like the foal or kangaroo, but we gradually achieve legginess." The bones increase in length, not so much by interstitial deposit, as by addition to their ends; that is, by progressive ossification of the layer of cartilage which intervenes between the end of the shaft and the epiphysis. Ossification goes on till the component parts of the bone are all united by bony matter, and thus the stature of the individual is determined. If from inflammation or injury an epiphysis be damaged, one limb may be shorter than the other, or inflammatory stimulation may even induce an increased length in the bone affected. The skeletons of tortoises, not being subjected to suddenjars, have no epiphyses at the ends of the long bones, whereas in the leaping frog the extremities of the humerus and femur long remain as separate epiphyses. The continuous concussions to which the ends of the bones of the lower limbs are exposed, when a vigorous child is excited by its own natural spirit to run about, are doubtless of great value in assisting the growth in length of the lower limbs, which soon lose their infantile character, and become adapted for running and walking. By exposing the lower limbs to the same influences and resistances during their entire growth we manage to maintain them of the same size and of the same length, and gentle jars upon the epiphyses at the joints may be considered favorable to growth.

Posterior Basic Meningitis.—By H. Thursfield. The article is an analysis of a series of cases seen at the Great-Ormond Street Hospital. The general conclusions are stated in the following: Posterior basic meningitis presents a considerable variety of clinical characters. In the majority of the cases which occur in children of under twelve months it is a very distinct and easily recognizable disease, but this rule does not hold invariably. On the other hand, a disease occurring in older children with many of the same symptoms and possessing the same pathological and bacteriological features, yet has certain characteristics which make it resemble very closely epidemic cerebrospinal meningitis. Are the two identical, and are the special features of the epidemic disease due merely to an exaltation of virulence in the organism? On the whole, and judging from the cases seen, the answer must be given in the affirmative. The clinical symptoms obviously differ considerably, without any corresponding alteration in the pathological or bacteriological features, and the main differences between the organism of Weichselbaum and the organism found in these cases in England seem to be quite insufficient to establish them as distinct species. If this view is accepted, we shall henceforth look upon posterior basic meningitis as a disease comparable in certain points to pneumonia, which, while as a rule a sporadic disease, occasionally presents itself in epidemic form. The causes which determine this variation are in both cases still to be discovered.

Gastric Hemorrhage and its Surgical Treatment.—By A. W. Mayo Robson. The conclusions the author reaches concerning the treatment of gastric ulcer are the following:

(1) All cases of acute uncomplicated gastric ulcer should be submitted to thorough medical treatment in the shape of long-continued rest and attention to diet, the patients not being allowed to get up or to resume solid food until at least a fortnight after all disappearance of pain. (2) When the ulceration persists and proves intractable to medical treatment, or when relapses occur, gastro-enterostomy should be performed so as to secure physiological rest and relieve the hyperacidity of the gastric juice nearly always found in such cases. (3) Perforation demands immediate surgical treatment. (4) The complications of disabling adhesions around the stomach and pylorus, pyloric contraction, and hour-glass contraction due to chronic ulcers leading to pain, dilatation, loss of flesh, and general impairment of health, now often treated as chronic indigestion, should be treated surgically. (5) In recurring, or so-called chronic hæmatemesis from gastric ulcer, surgical treatment is decidedly called for. (6) In acute hæmatemesis, further accuracy in diagnosis as to the size of the bleeding vessels is urgently needed; and the co-operation of the physician and surgeon is advisable in all cases of hæmatemesis, so that if relief be not obtained by medical and general treatment surgical means may be adopted if the bleeding is believed to occur from a large vessel; but seeing that capillary hemorrhage is capable of relief by medical means alone, medical should always precede surgical treatment. Abstracts of five clinical histories are given.

A Plea for the More Careful Study of the Symptoms of Perforation in Typhoid Fever with a View to Operation.—By William Osler. Early diagnosis and early operation may save from thirty to forty per cent. of cases of perforation. There are three groups of cases: (1) Those with infiltration and necrosis of the gut, so that the patient is not in a fit condition for operation; (2) those cases fit for operation in which it is successfully done, but the patient dies in the due course of the disease from the intensity of the fever or in a relapse; (3) those cases in which complete recovery takes place. The vital question is really not one of perforation, but one of consecutive peritonitis. The nurse should carefully note any complaint of abdominal pain, of hiccough, of vomiting, of sudden rise in pulse or respiration, of unusual sweating or of collapse. Careful attention should be paid, then, to the occurrence of abdominal pain, to the state of the abdomen, to the general condition of the patient, and to the blood count. Sudden pain, increasing in intensity and recurring in paroxysms, is perhaps the most constant symptom of perforation. With an increase in pulse rate, distention of the abdomen, increasing pain on pressure, and increase of leucocytes, the diagnosis is rendered probable. In a doubtful case, operation is indicated. A general anæsthetic may not be needed. In many cases cocaine has been used, with the occasional help of a whiff of chloroform.

Primary Carcinoma of the Ampulla of Vater with Report of a Case Presenting Some Special Features of Interest.—By H. D. Rolleston. The ampulla of Vater is the common channel inside the biliary papilla into which the common bile duct and Wirsung's duct from the pancreas open before entering the duodenum. We must distinguish cancer of this structure from (1) cancer of termination of the common bile duct, (2) of the termination of the duct of Wirsung, and (3) of the duodenal surface of the biliary papilla. Rolleston's patient was a man aged sixty-six years, with jaundice, enlarged liver, and some abdominal distention, but no ascites. The urine contained bile and some albumin, but no sugar. A diagnosis was made of cancer of the head of the pancreas. While in the hospital he was taken with symptoms of sudden collapse and died in eighteen hours. It was supposed that the gall bladder had ruptured. The autopsy showed a flat growth limited to the ampulla of Vater and occluding both the orifices of the common duct and the duct of Wirsung. The microscope revealed it to be a columnar-celled carcinoma invading the smooth muscular tissue about the ampulla. Additional points of interest in the case were the sudden onset of acute symptoms followed by death in eighteen hours, an extremely fibrotic condition of the pancreas, due probably to obstruction of Wirsung's duct, and an absence of glycosuria or diabetes.

On the Uses of Formalin in Glycerin.—By A. C. Jordan. The author finds that the use of glycerin as a vehicle for formalin overcomes to a great extent its irritating effect on the tissues. He uses a solution varying from one to four per cent. Under these conditions he has found formalin useful in applications to the throat, as a mouth-wash, as an application to the skin, and for urethral injections.

Foreign Body in the Abdomen.—By E. H. Ellison. The body proved to be a pair of catch forceps unknowingly left in the abdomen in an operation done some eight or nine months previously. Part of the blades had protruded through the integuments which had healed around them. This was removed in two different portions. The patient refused a cutting operation.

Arthritic Syndromes in Children.—M. Comby states that the three clinical syndromes—headache, vomiting, periodical fever—are indisputably of arthritic origin. The course of the paroxysms, the analyses of urine which have been made, the hereditary antecedents, and, finally, the treatment, confirm this pathogenic conception. For the attacks themselves there is little to do. There should be ordered prolonged rest in bed, liquid diet, warm baths, enemata, and injections of artificial serum. In the intervals between attacks, life in the open air, a sojourn in the country, in the mountains, at the sea-shore, physical exercises, practical hydrotherapy, friction, massage, alkaline cures, in some cases arsenical waters, and various other mineral waters, should be prescribed. The diet should be in greater part vegetable; bread, milk, eggs, vegetables both dry and green, fish and white meats, cooked meats, etc. For drinks, water or milk. There should be no excesses of any kind. Finally, hygiene of the lungs, digestive tract, brain, muscles, and skin should be observed.—*La Presse Médicale*, January 30, 1901.

The "Phototherapeutic" Cure of Lupus Erythematosus.—Levedde speaks of Nils R. Finsen's method of utilizing the chemical rays of the spectrum. The method is simple, consisting in leaving the patients exposed to the action of the luminous rays during two consecutive treatments of an hour or an hour and a quarter each. Since the writer began to apply phototherapy to dermatological complaints, he has had eleven patients afflicted with lupus erythematosus of the face; five of them are no longer under treatment, three being cured, and two improved in a remarkable manner. Six are under treatment, four of whom are improving greatly, while two have not yet received any real benefit. All of the patients were affected by a severe form of the disease. Almost all had been treated by all other known methods, with persistence, but without appreciable result. This method of Finsen's would appear to be the best treatment for severe forms of lupus erythematosus.—*Bulletin Général de Thérapeutique*, January 23, 1901.

Malaria and its Propagation by Mosquitos.—R. Bosquier believes that the theory of the transmission of malaria by mosquitos has so many proofs that there is a good chance of its being true and passing definitely into science. It must be recognized that the "mosquito-malaria theory" is in harmony with the greater part of the sayings of the old authors and the traditional precautions observed in malarial countries: not to travel by night, not to sleep in a room with open windows, to avoid the neighborhood of stagnant water where insects develop. But even if the mosquito theory cannot explain all the facts, nor even certain exceptional cases, nevertheless it can explain the great majority of facts and answer the problem of the habitual transmission of malaria. Prophylaxis inspired by it has already given proofs.—*Journal des Sciences Médicales de Lille*, January 12, 1901.

Cysticercus of the Eye.—Gallemaerts states that in certain cases it could be determined how long the cysticercus remained living in the interior of the eye; the longest period was seven years. The diagnosis is difficult in the beginning. The presence of the cysticerus is positively demonstrated only by the presence of movements. De Vincentiis has proposed to excite these movements, so as to render them more apparent, by applying a faradic current

to the temple. As soon as the diagnosis is made the extraction of the cysticercus must be proposed. This is the only way to preserve the organ and preserve vision. If the operation be performed early, the vision will be preserved in great part. As a prophylactic measure, meats should be more carefully inspected.—*La Policlinique*, January 15, 1901.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LATE QUEEN AND THE PROFESSION—SPECIAL MEETING OF MEDICAL AND CHIRURGICAL SOCIETY—LORD LISTER'S SPEECH—MEDICAL SOCIETY'S DEBATE ON TREATMENT OF TYPHOID—A MEDICAL ELECTION—BEER POISONING—OBITUARY.

LONDON, February 8, 1901.

THE funeral of Queen Victoria and the accession of King Edward with the attendant consequences have occupied more attention during the week than all other subjects. But your newspapers will have given you full details of these events, and I will confine my remarks about them to their medical aspect. I mentioned in my last the way in which the profession marked its feelings on the death of the Queen and, among the indications, how the Royal Medical and Chirurgical Society, meeting on the evening of Her Majesty's death, at once adjourned. Since the funeral, on Tuesday evening to be exact, a special meeting of this society was held to consider an address to the new sovereign. This was appropriate, as in the charter granted by King William IV. he declared himself and his successors, if they should think fit, the patrons of the society. The president (Dr. Pavy) said the late beloved Queen on her accession followed her predecessor and became patron, and the society now met to give expression to the feelings of all in an address of condolence, associated with the hope that his Majesty King Edward would in turn declare himself patron of the society.

Lord Lister, in moving the address, said that in common with the whole world, the society lamented the loss of a sovereign pre-eminent in wisdom and virtue, whose long reign was one constant, consistent effort to promote the good of her people and of all mankind. The signal success of her efforts was shown in the tributes to her goodness and greatness from all quarters at home and abroad. It was fit that the only royal medical society of her metropolis should give expression to their sense of grief at her death. The work of the profession, the relief and prevention of suffering always appealed to her warm, sympathetic heart. All her medical advisers would testify of the confidence she reposed in them.

Lord Lister here mentioned that he was, he believed, the only one who had had to exercise on her sacred body the art of surgery. The occasion was a critical and anxious one, but nothing could exceed her kindness and consideration, while she treated him with queenly dignity. But there was, he continued, another side to this address. In the night of sorrow they could see an auspicious dawn. The King in his first council meeting promised, in words characterized equally by dignity and pathos, to tread in the footsteps of his beloved mother, and had already repeated his promise in his messages to the entire empire. Various kindly acts indicated that the King inherited the grace and tact of the departed sovereign, and that he loved and honored the profession was evidenced in what he had done for Guy's Hospital and in establishing his "Prince of Wales' Hospital Fund."

The motion was seconded and carried unanimously, and the meeting separated.

The debate on typhoid fever at the Medical Society was opened with a paper by Dr. F. J. Smith, whose experience in the wards of the London Hospital and as senior pathologist gives importance to his views. The paper and discussion were on the treatment of the disease, the etiology and pathology being passed over. Dr. Smith is convinced that the lines laid down in our text-books are too strictly directed to the intestinal lesions, and he does not attribute the dangers of this solely to departures from routine milk dieting. The first thing he would prescribe would be rest in bed, with or without an aperient. He lays it down as a golden rule carefully to examine one stool at least in every twenty-four hours. The presence of undigested food would lead him to stop all food for twenty-four hours and then to begin with small quantities. If curds be present, milk in a raw state should be prohibited. Blood in small quantity should induce caution; in larger quantity indicates opium—say ten minims of the tincture every two hours for eight or ten doses, or till drowsiness is produced, all food being stopped for twenty-four or forty-eight hours. Sloughs without blood in quantity merely indicate a natural state of affairs in the third or fourth week of a severe case, but they suggest caution in feeding for a day or two. Feculent *débris* is the desirable constituent, and the less of the other substances named the better. Dr. Smith gives a fairly free range to the patient's appetite, making it almost the sole arbiter, in the absence of vomiting, hemorrhage, or tympanites. On the other hand, when there is no appetite he does not give food—but lets the patient have cold water—the only thing the latter craves. Dr. Smith then described more fully the dietary he advised in various conditions. Properly made beef tea or beef juice, he thought, could not be equalled by the commercial substitutes in vogue. He would not withhold beer from a patient in the typhoid state who craves for it, but other forms of alcohol are drugs for emergencies.

Turning to the complications, Dr. Smith said vomiting was generally due to putting food into the stomach when there was no appetite, and restriction to water should be enjoined. Tympanites and constipation should not occur if the dietary is right and aperients are employed. If the bowels are not opened once in twenty-four hours sodium sulphate in two-drachm doses is given every two hours until it acts. Perforation gives a chance to surgery, but it is a poor one. Diarrhœa if excessive is often due to extensive ulceration of the colon, and is then a very fatal complication; but it may also depend on undigested food. This will be shown by careful inspection of the stools, and must be treated by stopping everything except water. Six to eight motions a day do not constitute diarrhœa; they are part of the natural history of the disease and they occur in most cases that end in recovery. In hyperpyrexia he prefers tepid baths. Hemorrhage needs only starvation and opium. Tannin and other drugs are useless or worse. With regard to anti-inoculations Dr. Smith's attitude seems to be one of hopeful expectancy.

Dr. Sidney Phillips endorsed much of Dr. Smith's view. He had brought forward cases in which no intestinal lesion was present before the bacillus was discovered. The stress of the disease might fall on the kidneys, lungs, or central nervous system. For hemorrhage hamamelis was sometimes useful, and it did not paralyze the intestines.

Dr. Isaac had been disappointed with tepid sponging in pyrexia. Dr. Pope suggested suprarenal extract in hemorrhage.

Dr. W. Hunter held that the disease had been milder of late years, but not as a result of treatment. He believed that septic inflammation played a part in perforation as well as the bacillus, and agreed with Dr. Smith that calomel was the best intestinal antiseptic. Dr. Hadley thought pulmonary lesions were more often fatal than intestinal, and that cardiac failure was the result of toxæmia and pyrexia.

Dr. F. J. Smith in his reply repeated that he had seen benefit follow the continuous bath at 99° to 100° F. He doubted whether solid food had ever caused perforation.

There has been an election to the General Medical Council in Ireland, for the seat held by Sir W. Thomson. He has been re-elected for a further term by an enormous majority over Dr. Laffan, who opposed him on a medical-reform platform.

Beer poisoning is exciting further interest. Selenium has been detected as well as arsenic, and would add to the virulence of the liquid.

Dr. Leslie Ogilvie died on the 2d inst., aged forty-eight years. He was lecturer on comparative anatomy at the Westminster School and physician to one of our children's hospitals. He translated Fehleisen's "Erysipelas Narcosis" and contributed various papers to the journals.

Dr. John Edward Pritchard, of Bristol, died on the 2d inst., aged fifty-one years. He was an Oxford graduate and surgeon to Horfield prison. He belonged to a medical family and was much esteemed.

CATARRHAL PNEUMONIA IN CHILDREN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The MEDICAL RECORD quotes Dr. H. Illoway as being certain that "pneumonia, both catarrhal and croupous, in infants and children," can be aborted by the use of aconite and veratrum viride. For the past twenty-five years I have used both these remedies in the treatment of pneumonia of adults, as well as of infants and children, and always with eminent satisfaction. I, however, give aconite only in the initial or chilly stage. I have found the remedy par excellence, in all these cases, to be veratrum viride and mercury bichloride, combined in syrup. For the first twenty-four or forty-eight hours I repeat the dose hourly; and if the disease is not aborted (as it often is) in that time, the way is made easy to a quick recovery.

THE PUPIL AFTER DEATH.

By J. E. COURTNEY, M.D.,

POUGHKEEPSIE, N. Y.

Ordinarily the pupils are quite widely dilated and about equal after death, and shortly become fixed in a position of moderate dilatation. But whoever has done many autopsies and looked carefully at the pupils will certainly have noticed that there are many exceptions to this rule. My own observations convince me that in certain cases of disease of the brain or its membranes the pupils may retain after death the impress of the condition imparted to them by the disease which caused dissolution. If this fact could be established, and the data formulated, it would be highly interesting and of use in immediately suggesting the cause in cases of persons found dead, and in cases of persons dying without having had a physician in attendance. There appears nothing inconsistent in the idea of the muscular fibres of the iris becoming fixed in about the position in which they were at the time of death. I have seen this phenomenon in the following conditions, commented upon the size of the pupils before autopsy, and seen the condition which they suggested found.

1. In persons dying of large cerebral hemorrhage, the pupils were large on the side opposite the lesion and remained perceptibly so at autopsy ten or twelve hours after death.

2. In cases of death from paretic dementia with a general meningo-cerebritis and adhesions of the pia to the convolutions, the pin-point pupils seen in life were unchanged at autopsy.

3. In the condition of pachymeningitis hæmorrhagica the pupil contracted on the side of the hemorrhage has been repeatedly found so at autopsies.

ANEURISM OF THE PULMONARY ARTERY, WITH REPORT OF CASE.

By B. C. LOVELAND, M.D.,

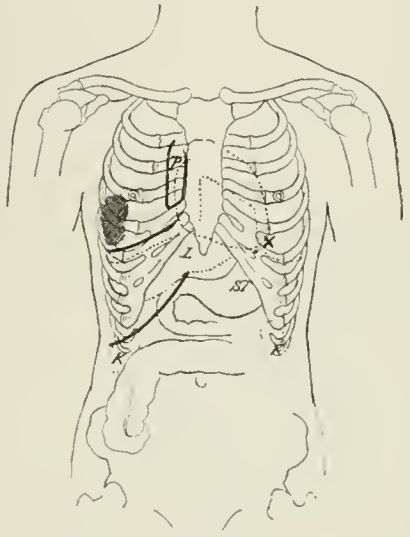
SYRACUSE, N. Y.

Mr. A. D. H——, forty-one years of age, native of the United States, came under my observation May 2, 1900. His previous illnesses were gonorrhœa, catarrh, cankers in the mouth, and blood poisoning, which occurred two years ago. He denied ever having had a chancre, but his family physician told me that he undoubtedly had specific disease at one time. His heredity was good. He dated his present illness from a sharp attack of pain in the right side of the chest, extending into his right shoulder and arm, which occurred on January 15, 1900. His pain was attributed to a strain in trying to catch an armful of clothing which fell while he was handling it, his business being that of a clothing merchant. There was no swelling of the arm, nor any pain on motion. Pain was very severe for two or three days and nights, and was attended with great dyspnœa, so much so that he was obliged to sit up night and day to breathe. He had not been entirely free from pain since for any length of time, and I was consulted especially in reference to this pain. He had lost no flesh, and was apparently well nourished. He had occasional cough but no expectoration. Both cough and dyspnœa could be produced by walking a little fast, or climbing a few steps. He said he had never been able to run like other men, on account of shortness of breath. The tongue was coated on the back portion. Pulse 82, regular and compressible; bowels regular; urine scanty and high colored; pupils equal and normal.

Physical examination of the chest showed dulness on percussion over a portion extending from the second to the fifth rib, and for two or two and one-half inches to the right of the sternum; over this area also a distinct bruit could be heard. There was some dulness also on percussion, and many small râles could be heard near the axillary line and extending as low as the seventh rib. The area of liver dulness was slightly enlarged. A small mitral murmur could be detected. The bruit was not conveyed to the carotid artery (see diagram).

Pulsation could be felt over a much larger area than that described as an area of dulness, and could be seen easily on looking across the chest. The *x*-rays gave negative results in this case.

A diagnosis of aneurism was made, and the patient was made to rest, put on a diet of concentrated food,



and given iodide of potassium. After two or three visits he ceased to come, as he lived in a neighboring city, and I heard nothing further from him until he died suddenly on September 19, 1900, and I was asked to assist at the autopsy, which showed results as follows: The body was well nourished. Slight bulging was noticeable under the right clavicle, and an apparent fulness in the right side of the chest. Subcutaneous fat was moderate in amount. The undertaker, in attempting to tap the heart, drew off a large amount of fluid blood. The left lobe of the liver extended to the line of the left nipple. The pericardium was adherent. There was a large blood clot, about three quarts, in the right pleural cavity. The right lung was somewhat pigmented, and much compressed in the middle lobe: otherwise normal. The pulmonary artery was dilated throughout, its walls were thin, and it had a gritty feeling from calcareous deposit, and a clot extended into the lung. There was an aneurism of the right pulmonary artery, before its entrance into the lung, which had ruptured, causing fatal hemorrhage into the right pleural cavity. This sack was situated somewhat transversely to the artery, and was three and one-half or four inches in its longest diameter, by two or two and one-half inches in its short diameter. Its walls were thin, semi-transparent, and partially covered with organized clots. The heart was normal in size, the tricuspids were normal, and there was a slight mitral insufficiency. Both aortic and pulmonary valves were normal. There was atheromatous deposit in the aorta, pulmonary artery, and both mitral and tricuspid valves. The diameter of the pulmonary artery at the cardiac end was about one and one-half inches, and at its entrance into the lung nearly an inch.

The rarity of this case and its interesting character

have prompted a brief study of pulmonary aneurism in its various forms.

Pulmonary aneurisms may be divided into four classes or varieties.

First. General dilatation of the artery and its branches. This variety may not always prove the cause of death.

Second. Sacciform or fusiform aneurism, situated within the pericardium, in which variety death results from rupture into the pericardium.

Third. Sacciform or fusiform aneurism, situated between the bifurcation and the entrance of the artery into the lungs. In this class rupture occurs into the pleural cavity.

Fourth. Those cases of aneurism, mostly small, in connection with tuberculous cavities in the lungs, which terminate in uncontrollable and fatal hæmoptysis, and which have been so well studied by West[1] and Kidd,[2] of London, and Osler[3] in our own country.

Pulmonary aneurism of the first variety mentioned, general dilatation, is not common; only one case being reported among those I have had opportunity to look up; though some of the earlier writers thought it was comparatively common it has not proven so in the autopsy room. The case reported by Sydney Coupland, M.B.,[4] is worthy of notice here, as it belongs to this class, and has been misquoted by Williams[5] as a case of sacciform aneurism. Coupland's case was one of extreme dilatation of the pulmonary artery, disease of the pulmonary valves, patent foramen ovale, bronchitis, emphysema, and partial hemiplegia, in a man seventy-five years old. No diagnosis of aneurism was mentioned as having been made before death, and the patient died in a comatose or semi-comatose state, and no rupture of a blood-vessel was found at the autopsy. He had albuminuria and general atheromatous degeneration. In this case the emphysema made it impossible to outline the cardiac area by percussion.

The second variety, sacciform or fusiform dilatation, situated within the pericardium, is referred to by several of the writers on the practice of medicine and physical diagnosis, and the signs and symptoms are clearly given. However, the proposed differential sign between aortic and pulmonary aneurism, by determining whether the left or right side of the heart is hypertrophied, would not always be of value, for in Coupland's case, referred to, emphysema altogether obscured the cardiac dulness.

The earliest case of this variety I have found was reported in a French publication in 1822,[6] and occurred in a man of robust constitution, thirty-eight years of age. No symptoms of aneurism preceded his fatal illness, which followed a severe attack of seasickness and gastritis, accompanied by much and severe vomiting and straining. Autopsy showed the pericardium full of blood from the rupture of an aneurismal sack which had developed from the pulmonary artery.

The third variety, sacciform or fusiform aneurism, situated between the bifurcation of the artery and its entrance into the lung, is very rare, and is illustrated by the case reported at the beginning of this paper. It is not described in any of the text-books, so far as I can find. The first case of the kind reported is found in the works of Ambrose Paré,[7] for the translation of which one may refer to a Sydenham Society publication of 1844.[8] On account of the careful description and quaint language, as well as the rarity of the case, I will quote from the report of Paré:

"Aneurisms that occur in the internal parts are incurable, happening frequently in those who have had the pox, and have been sweated several times, by which means their blood has been very greatly heated, and rendered thin, which occasions that within the arteries to escape, and to dilate the body of the vessel, sometimes to the size of the fist. Which I have seen in the body of a man named Belanger, a master tailor, living on the bridge of St. Michael, near the sign of the Cock, who had an aneurism of the pulmonary artery of which he suddenly died, in consequence of the artery bursting whilst he was playing ball. On dissecting him I found a large quantity of blood effused into the thorax, the body of the artery dilated to the size of a fist, and its lining membrane quite ossified. This I exhibited shortly afterward at the School of Medicine, where those who saw it were greatly surprised, and on this account I keep it in my museum as a monstrous thing. Belanger while he lived had a very strong pulsation in his arteries, and he felt extreme heat in the body, and often fainted. M. Sylvius, the lecturer on medicine, had ordered him to discontinue his wine, and only drink boiled or pure water. He chiefly lived on fresh cheese, and the same was applied in the form of a poultice to the seat of pain. In the evening he took pearl barley, mixed with barley flour and poppy seeds. Occasionally refrigerant clysters were administered, or simply bruised barley." He adds, "and he told me that from no other physician had he received so much benefit as from Sylvius."

It will here be seen that, at so early a time as the report of Paré, the rôle of syphilis in the etiology of aneurism was well understood, and here also we find that, while he regarded internal aneurisms as incurable, he attributed much benefit to abstinence from stimulants, sedative remedies, and a concentrated albuminous diet.

The only other case belonging to this variety, which I have been able to find, is that reported by Rosner,[1] which was the same in location and termination, but differed in that it was caused by tuberculous ulceration, Rosner believing that it was the seat of primary tuberculous lesion. It may be well to state as an odd fact that no report has been found of an aneurism of this class in the left pulmonary artery.

As this variety of aneurism is not described in the text-books, I will briefly mention the signs which should lead to a diagnosis. Pain, in character like that accompanying other aneurisms, but not so deep-seated as in aortic disease, not increased by breathing or motion; cough on slight exertion, but no expectoration; either congestion, with râles, or emphysema of the lung—these should lead to a thorough physical examination with suspicion of disease of the pulmonary artery. Physical examination should reveal a bruit, not conveyed above the clavicle, more or less dulness on percussion, and pulsation if the tumor has reached sufficient size, diminished respiration where the lung is compressed, and râles, either mucous or whistling, in other parts of the affected lung. The pulsation will be felt, and the bruit heard, to the right of the sternum, just above or below the third rib, if the aneurism is of the right artery, and if the left is the seat of disease it will be to the left of the sternum, not far from the position noted in the descriptions of aneurism of the common pulmonary artery.

The pain, in the case that I have reported, was described to me as very much like the pain of angina pectoris except that it affected the other side and arm.

The fourth variety, aneurisms, generally small, in connection with tuberculous cavities, is very frequent,

has been abundantly studied, and comprises by far the greater portion of the reported cases, some eighty in all, that I have found, in looking up the subject. They are usually not larger than a cherry and occur singly, but there are exceptions, both as to size and the number in the same person, as for example the case reported by Kime,[1] in which the aneurism was large enough to be diagnosed by physical means, more than a month before death; and the cases of Kidd, to whose work I have already referred, who found, in two hundred and thirty cases of fatal hemorrhage, twenty-six aneurisms, and in four of these there were multiple aneurisms. All agree as to the difficulty of diagnosing these small aneurisms, and both Kidd and West consider severe and uncontrollable hæmoptysis the only sign which may probably point to the rupture of one of these small aneurisms, as they are generally too small to be discovered by physical methods of exploration.

Sufficient has already been said in relation to the diagnosis of these cases, and as the pathology, etiology, and treatment are much the same as in other internal aneurisms, it is not necessary to go into those divisions of the subject in this paper.

BLUNDERS IN CARING FOR PARTS OF THE BODY INTENDED FOR CHEMICAL EXAMINATION.

By EDWARD BARTOW, Ph.D.,

UNIVERSITY OF KANSAS, LAWRENCE, KANSAS.

During the past two years it has been my fortune to do the analytical work in some cases of suspected poisoning. Some of the physicians who performed the autopsies apparently lacked knowledge of proper methods of caring for the organs removed. For this reason, the publication of the mistakes made, together with a brief outline of the correct methods, may prove of use, for when the organs are placed in the hands of the chemist, there should be no possible chance to suspect contamination.

In one case that was brought to me, a case of suspected arsenical poisoning, the physician in charge had a can specially prepared from sheet tin for the reception of all the organs removed. I examined the organs submitted (stomach, liver, and heart), finding no poison except arsenic, and that in only a small amount, as follows: 0.96 mgm. to 100 gm. of tissue of stomach, 0.72 mgm. to 100 gm. of liver, 0.21 mgm. to 100 gm. of heart. Nothing in the contents of the stomach.

Since it is well known that sheet tin contains more or less arsenic, I thought it advisable to examine it. By dissolving the tin in nitric acid a trace of arsenic was found on submitting the solution to the Marsh test. When the tin was kept in contact with water or an alkali for several hours, there was extracted nothing that would show arsenic by the Marsh test.

In this case the body had not been embalmed, therefore it was possible to have it exhumed and other organs obtained for analysis. It was thus unnecessary to rely on the probable non-solution of the arsenic in the fluid accompanying the organs. This time I found 0.70 mgm. in 100 gm. of the kidneys and traces in the brain.

I learned afterward that the attorney for the defense had sent some tin, supposed to be of the same kind, to a chemist for analysis, and that that chemist had reported no arsenic.

In another case there was an absurd error which proved to be of no moment since no poisons were found in the organs examined. This time the coroner and a druggist took the glass fruit jars containing the organs, closed and sealed them; then for some unexplainable reason, they wrapped them in cotton soaked in embalming fluid. When asked as to the possibility of the fluid containing poison, the druggist said it might be poisonous to drink, but not to touch, as they sometimes used it for washing their hands. An examination of the cotton showed large quantities of arsenic. To prevent, if possible, the arsenic on the cotton from reaching the contents of the jars, the jars were thoroughly washed by allowing a stream of water from a faucet to flow over them for five minutes, then the contents were removed without allowing them to come in contact with the mouth of the jar. An examination of the contents then failed to reveal the presence of any poisons. If arsenic had been found, there would have been grave doubt as to its source.

Probably not many physicians are called upon to take charge of a case of homicidal poisoning. If possible an expert should be employed. Nevertheless, every physician ought to know what to do if such a case should come to him.

A brief summary of the directions for caring for the parts removed, as given in the "Medical Jurisprudence and Toxicology" of Witthaus and Becker, vol. iv., p. 113, is as follows:

Each of the parts removed should be placed in a new glass jar, which has been well rinsed out with water, and which is to be closed with a glass cover or stopper, or with a cork tied over with moistened bladder or parchment paper. A cord or tape is then to be tied about the jar, then so fastened by sealing-wax bearing a private imprint that it is impossible to gain access to the contents without breaking the seal or cutting the tape. No preservative should be added unless the parts must be kept for several days before transmission to their destination. Under these undesirable conditions alcohol only may be used, and if used, a sample of at least a litre should be separately submitted for analysis.

In removing and transmitting the parts destined for analysis the examiner should exercise the minutest care to prevent the possibility of error, contamination, or loss.

ISCHIO-RECTAL ABSCESS, COMPLICATED WITH GANGRENE AND PRIAPISM.[1]

By H. H. HARALSON, M.D.,

VICKSBURG, MISS.

James W——, white, male, aged sixty-eight years, became ill about the 25th of August, and was seen by his family physician. He complained of pain in the region of the anus, and had some fever, not high, and a slightly accelerated pulse. This condition continued for several days. Frequent rectal examination by his physician revealed nothing. Pain in the region of the anus continued with increased severity.

September 1st: No induration could be felt in the rectum or around the anus by the attending physician. On the second day of September, at the morning visit, the temperature had gone up, the pulse was much more accelerated, and the pain was greatly increased. Induration and redness existed around the anus. Another rectal examination revealed nothing more. In the afternoon the temperature had reached 105° F. in the axilla, the pulse was weak and rapid, there was retention of urine, and a very painful priapism had developed.

September 3d: Temperature, 105.5° F.; pulse very much weaker; priapism still present. An incision about an inch long was made to the left of the anus

[1] Read before the Vicksburg Medical Association.

and a quantity of offensive pus and fecal matter evacuated. The temperature rapidly declined to normal. The priapism continued, and retention of urine changed to incontinence. September 4th the patient was in about the same condition as on the 3d.

I saw the patient on September 5th at 10 o'clock P.M. in consultation. The temperature was then 101° F.; pulse, 100 and very weak. The patient was in a semi-unconscious condition, involuntary discharges had occurred from the bowels and bladder, and priapism was still present. Examination per rectum gave no evidence of induration; the prostate was very much enlarged. I introduced my finger into the wound, and found a large cavity extending in front and behind the rectum. I enlarged the wound, making it about three inches long, and found an opening into the rectum some two or two and a half inches above the anus. The discharge was extremely offensive and characteristic. The entire surface of the cavity was thickly covered with a dark gray mould, or "decomposed tissue, retaining some of its histological or anatomical properties"—moist gangrene. I scraped and cut away as much of this dead tissue as possible and washed out the cavity, first with hydrogen peroxide and then with a solution of bichloride of mercury 1 : 2,000, and dressed with iodoform gauze.

September 6th: 6 o'clock A.M., the patient was still unconscious; the temperature was slightly above normal; pulse, 80 and weak; involuntary discharges continued from the bladder and bowels, and priapism continued. On the opposite side of the anus I noticed a dark spot about the size of a silver dime. With the end of a probe pressed against the centre of this spot an entrance was easily gained. With a bistoury I cut about one inch backward and then an inch forward. This opened up a large subcutaneous sac, also covered with a dark gray mould, and connecting by sinuses anteriorly and posteriorly to the rectum with the one on the opposite side. This was treated in the same manner as the cavity on the opposite side. The extension of the gangrenous process continued until almost the entire perirectal tissue became involved. The patient died thirty-six hours after I first saw him.

Gangrenous periproctitis is not an uncommon affection, but usually follows traumatism. In this case, however, there was no history of an injury, but an indistinct history of a prostatitis extending over several months. If the clinical evidence obtained by the attending physicians, and upon which the foregoing notes are based, is correct, this was doubtless a case of chronic ischio-rectal abscess of probable tuberculous origin, which became infected with pyogenic organisms, and on September 2d gave the first evidence of acute symptoms.

I would not undertake to account for the priapism unless it was due to vesical or pelvic irritation, which is sometimes the cause.

The Effect of Local Hyperæmia Produced by Heat on Chronic and Infectious Ulcerations.—K. Ullmann ascribes great value to the application of dry heat of high degree to sluggish ulcerations of all kinds. The temperature should range from 80°–150° C., and is to be applied by special apparatus which allows accurate graduation of the temperature and the rapid absorption of all moisture. As long as the skin is kept dry no pain is caused, and the sensation is even said to be an agreeable one. The method is especially adapted for use in cases of venereal and other affections of the genitals, and while acute and mild lesions are more conveniently treated by the ordinary means, in chronic, obstinate, serpiginous, or gangrenous cases the effects are extremely satisfactory.—*Wiener klinische Wochenschrift*, January 3, 1901.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Sixty-first Regular Meeting, Held on Friday, February 1, 1901.

A. Alexander Smith, M.D., President, in the Chair.

A Case of Universal Peritonitis following Ruptured Duodenal Ulcer: Operation Twenty-seven Hours Later; Recovery.—Presented by Dr. Robert Abbe. The patient was a young man who was returning home from business on November 8th last, and was apparently in perfect health when he stepped off the train of the elevated railroad. As he started to walk across the platform of the station he was suddenly seized with an intense pain in the abdomen, which doubled him up and was so severe that he had to be help downstairs. He was given a little whiskey and then assisted to a friend's house, where he remained until evening. He vomited the whiskey which he had taken, and as his pain did not improve, he sent for his family physician, Dr. J. Harvie Dew, who suspected that the case was one of acute appendicitis, and gave him some morphine. The patient passed a bad night, and when Dr. Abbe saw him, about noon on the following day, his condition was exceedingly grave. The entire abdominal wall was rigid and distended, and there were well-marked evidences of a universal peritonitis, with tenderness everywhere, but most pronounced in the epigastrium. The diagnosis lay between acute appendicitis with rupture, and perforating gastric ulcer. On account of the nearly hopeless condition of the patient, Dr. Abbe asked Dr. Bull to see him with the speaker, and upon consultation it was decided that the patient was entitled to the slight chance which an operation held out. At this time his pulse was 120 and weak; his temperature was 102° and had remained stationary for three hours, which was looked upon as somewhat hopeful. The abdominal distention had increased.

Operation: Without further delay a median incision was made from below the umbilicus downward, and when the abdominal cavity was opened a large quantity of turbid fluid presented. This was not offensive, but the pelvis below was filled with yellow pus. The intestines were angry and inflamed in appearance, and this condition was shared by the appendix, but this was not perforated. In order to be on the safe side, however, it was removed. It was found to be absolutely solid and distended with lymphoid tissue. Dr. Abbe said this was the only specimen of the kind that he had ever seen. The removal of the appendix was accomplished through a small lateral incision. As it was evident that this organ was not the cause of the trouble, a third incision was made in the median line, from a point just above the umbilicus upward. The omentum was crowded up against the half-empty transverse colon. When the colon was drawn down a quantity of foul matter was seen coming from below the stomach, and this also filled the space between the liver and stomach. The liver was coated with lymph and separated from the diaphragm by a space of air. The entire abdominal contents showed evidences of infection. About an inch and one-quarter below the pylorus a rupture of the duodenum was found; it was about the size of an ordinary lead pencil and was freely discharging gas and a slimy secretion. After the tissues around it were cleansed, it was surrounded by a double row of purse-string sutures, the second row being inserted so as to bury the first. The peritoneal cavity was then thoroughly cleansed, large quantities of hot salt solution being thrown into the three openings

through a Chamberlain tube. After both surfaces of the liver and all the fossæ of the peritoneal cavity had been irrigated and both the upper and lower surfaces of the omentum had been cleansed, the latter was drawn downward, in order completely to cover the small intestines, and thus prevent the interference with peristalsis, which was so apt to occur when the intestines were covered with gauze. A large tube was inserted into the upper opening and kept there by liberal iodoform-gauze packing, and a glass tube with gauze tamponade was left in the pelvic opening. The patient made an uneventful recovery from the operation. His temperature on the day after the operation was 101.5°, and rapidly fell to normal. The glass tube was left in several days, and the last piece of gauze was removed in two weeks.

Dr. Abbe said that in a recent paper on this subject by Dr. Robert F. Weir, there was a report of fifty-one cases of perforating duodenal ulcer which had been operated on, with seven recoveries. In twenty-five of the fifty-one cases the ulcer was found and closed; in the remaining cases it was not found at the time of operation, and all the patients died. Of the seven recoveries, all were operated on within thirty hours—most of them within six hours. The most striking symptom in the majority of these cases was the very sudden onset of the pain; it was violent and instantaneous, coming on without premonitory symptoms, while the patient was walking or straining, or upon making a false step. In most of the cases vomiting was a prominent symptom. The symptoms progressed rapidly to a fatal termination. If an operation was done within the first six hours, about twenty-five per cent. could be saved.

A Case of Exophthalmic Goitre with Suppuration of Both Corneæ, Ending in Total Blindness.—Reported by Dr. Charles Stedman Bull. The patient was a married woman aged thirty-two years, whom he had first seen in November, 1894. About one year before he had seen her, she had been prematurely delivered of her third child at the eighth month of pregnancy, and was very ill with what was probably, from her account, post-partum hemorrhage. She had prolapsus uteri, which required some operative interference for its relief, and she almost immediately became pregnant again. During the fourth month of this pregnancy, both eyes took on a staring appearance and began to protrude, and, as she expressed it, her throat began to swell. She became very nervous and short of breath, having at times attacks of dyspnœa which were asthmatic in character. Her heart beat very rapidly, and her general health failed. When Dr. Bull saw her, she presented all the signs of a typical case of exophthalmic goitre. Both eyes were very prominent, the protrusion being directly forward. Von Graefe's sign was present, an important symptom in the early recognition of the disease. Dalrymple's sign was strongly marked, the upper lids being retracted, and the conjunctiva oculi was very hyperæmic. The media were clear, the vision was normal, and the retina was very hyperæmic. Both lateral lobes of the thyroid gland were very much enlarged, the right more than the left, and evidently exerted some pressure on the larynx and trachea. The respiration was very rapid, 30 to the minute, and shallow. There was marked tachycardia, and a loud blowing murmur was heard over the base, which was probably anæmic. She was advised to come into the hospital for treatment, but as she was near her confinement she decided to remain at home. She was immediately put on iron and pilocarpine internally, and carefully watched. She passed through her confinement safely, and at the end of the third week persented herself again for treatment. The tachycardia was somewhat less marked, and the respiration less rapid and deeper, but the exophthalmos was unchanged. She presented herself once a week for treatment until April, 1895, when the speaker went off duty, and he did not see her again until February, 1896. She was then again pregnant, and came with a severe inflammation of both eyes, which had evidently begun as ulceration of the cornea, which had rapidly gone on to suppuration. The abscesses had involved the entire cornea in each eye, and both corneæ had sloughed. There was, of course, total loss of sight, and as there was no perception of light in either eye, there had probably been total detachment of the retina as a result of the perforation of both corneæ, and the sudden loss of intra-ocular tension. The eyeballs were still very prominent, the upper lids in a condition of extreme retraction, the thyroid was about in the same condition as when he had last seen her, and the tachycardia very marked (160). The ruptured eyeballs had nearly healed up by new masses of exudation when he saw her, but the case was of course hopeless. During the time that she was under treatment at the infirmary she was advised to enter the hospital wards, and have an operation for tarsorrhaphy performed for the purpose of narrowing the widened palpebral fissure, and thus diminishing the dangers resulting from the lagophthalmos, but this was declined.

The Treatment of Chronic Rheumatic and Allied Joint Lesions, with Deformity as Complication.—Dr. V. P. Gibney read this paper (see page 321). In connection with his paper, Dr. Gibney exhibited a Campbell knee brace, and the apparatus known as the kyphotome, which is used in the correction of a rigid spine.

Dr. George L. Peabody said he was a little disappointed with Dr. Gibney's wholesale condemnation of the hot-air treatment, which the speaker said he had employed in quite a number of cases of chronic rheumatism with very happy results. In rheumatoid arthritis, which was a totally different disease, the hot-air treatment had not proved very helpful.

Dr. Walter B. James said there were few fields in medicine where our therapeutics were less satisfactory than in the class of cases discussed by Dr. Gibney. The speaker said that in his own experience these patients usually received more benefit in the long run from passive motion, regularly carried out, than from fixation and inactivity of the affected part. Of course, such a method of treatment could prove beneficial only in chronic rheumatism with ankylosis, rather than in rheumatoid arthritis. Dr. James said that another plan of treatment which he had found of some value was the use of vapor baths, taken in the india-rubber cabinets. These had been tried in cases of chronic rheumatism at the Presbyterian Hospital with very gratifying results. Even the slightest aid in the treatment of these rather hopeless disorders should be welcomed.

Dr. Charles L. Dana said his experience in the treatment of this class of disorders was limited chiefly to cases of rheumatoid arthritis in some of its forms; for in its earlier stages the symptoms of this disease were often obscure and associated with nervous disturbance. In the treatment of its resulting deformities, the employment of much force or the use of plaster of Paris had not been successful, and he had given it up. Rheumatoid arthritis being a degenerative trouble, not an inflammatory one, the adhesions were secondary and breaking them still left the degenerated joint. Baths, massage, and all sorts of active manipulation were usually only of temporary use. Under tonic treatment and rest, however, with plenty of fresh air and improved hygiene, these patients often did remarkably well. In the traumatic class of cases, or those associated with psychoses, the symptoms sometimes proved most obstinate and puzzling. Such pa-

tients were usually best left alone, and encouraged to keep their minds away from their joints.

Dr. Beverley Robinson said he would be very glad to learn of any mechanical device which would prove helpful in the deformities resulting from rheumatoid arthritis or chronic rheumatism. The speaker said that in the treatment of these cases he had always relied upon proper medication, with fresh air, good food, massage, and a limited amount of motion of the affected part. This treatment usually proved unsatisfactory, but it was the best he knew of. Dr. Robinson asked Dr. Gibney whether he applied the plaster of Paris directly over the skin, or whether an ordinary bandage was interposed between the two.

Dr. Gibney said he preferred to put it next to the skin, which should first be well greased with some sterilized salve. If the plaster produced an eruption, as it did at times, it could be applied over a thin cheese-cloth bandage. When it was applied directly to the skin, it fitted more closely than when it was put on over a bandage, and we got more perfect immobilization of the part and consequently there was less likelihood of further adhesions. Dr. Gibney said he had kept the plaster next to the skin for a period of six months without doing any harm.

Dr. Robinson asked Dr. Gibney what he thought of the so-called douche-massage treatment, which was practised extensively at Aix-les-Bains and also at Hot Springs.

Dr. F. P. Kinnicutt asked Dr. Gibney whether he applied similar methods of treatment to cases of chronic rheumatism and what was known as rheumatoid arthritis, or whether he made a distinction between the two.

Dr. Gibney said that in rheumatoid arthritis the treatment should be less forcible than in chronic rheumatism, in order not to excite further inflammation of the bone, and the immobilization should not be kept up so long. The speaker said he usually immobilized the affected part until he thought passive motion could be employed with safety. Dr. Gibney said he fully realized the difficulty in the management of cases of rheumatoid arthritis, which he agreed with Dr. Dana was a degenerative disease. Still, when these patients were practically helpless, with distorted limbs, at least an effort should be made to straighten the latter so that they might serve some useful purpose. In the neurotic class of cases, to which Dr. Dana referred, very little could be accomplished by mechanical treatment, and such patients might get well over night. The speaker said he had in mind a woman who belonged to this class of cases, and whose lameness was rapidly cured by insisting upon her receiving daily treatments from a masseuse whom she cordially hated. Dr. Gibney said he had had no experience with the douche-massage treatment referred to by Dr. Robinson. The hot-air method he had given a very fair trial, both in private and hospital practice, and he had been led to the opinion that it did not do much good either in chronic rheumatism or in rheumatoid arthritis; at least, it was no more beneficial than massage or hot fomentations or hot steam baths.

Dr. Peabody said he felt quite sure that he had seen good results from the douche-massage treatment in cases of chronic rheumatic arthritis—not in rheumatoid arthritis. He recalled one case in particular, that of a man suffering from chronic rheumatism, in whom the disease had progressed to such a degree that he had to be carried to and from the steamer. After several visits to Aix-les-Bains he came back apparently cured and was able to resume his business.

Dr. Kinnicutt said he was familiar with the case referred to by Dr. Peabody, and could corroborate the statements regarding the beneficial effects of the treatment by the douche-massage method at Aix-les-Bains. Before the patient went to Europe, he was absolutely helpless, being unable to rise from his chair. After undergoing two courses of treatment there he returned home practically cured, and could walk as well as ever. In the course of a year or two, however, his symptoms returned; he again submitted to a course of treatment in France, but without receiving much benefit, and he was now a hopeless invalid, being worse off than he was at the beginning. There was no doubt, Dr. Kinnicutt said, that a certain class of these cases were greatly benefited by the treatment at Aix-les-Bains. It was doubtful at first whether the case referred to was one of chronic rheumatism of a grave type or a case of rheumatoid arthritis; at the present time the patient presented the typical clinical signs of a rheumatoid arthritis in its advanced stage.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 21, 1901.

Robert F. Weir, M.D., President.

The Rôle of the Colon Bacillus in Human Affections.—Dr. A. J. Lartigau read this paper, treating of the different varieties of this bacillus as one form. He said that we now knew that it was one of the most widely distributed micro-organisms in nature. Its presence in the mouth had been frequently demonstrated. Post-mortem invasion of various organs was a constant phenomenon, and this vitiated many of the bacteriological studies made after death. If the colon bacillus were enclosed in a loop of intestine that had become strangulated, it would soon become quite virulent—indeed, some observers stated that almost any abnormal condition of the mucous membrane of the intestinal tract increased the virulence of this organism. The normal intestine provided food in a favorable form for assimilation by this bacillus, but it did not become virulent, because its first force was spent upon the process of fermentation. Not a few instances had been recorded in which the bacillus had been present throughout the body, and had given rise to a general infection. Numerous cases of hemorrhoidal phlebitis had been reported as a result of infection with this bacillus. Endocarditis had been shown by certain French observers to result occasionally from infection with the colon bacillus. It had been thought to be a factor in the diffused diseases of the intestine, especially infectious enteritis, because of its presence in such cases in considerable number. In traumatic lesions of the intestine, the colon bacillus evidently played an important part. There had been a disposition to look upon this bacillus as the cause of peritonitis, but within the last few years the opinion had gained ground that the infection of peritonitis was multibacterial. It was now generally accepted that most cases of appendicitis began as a local inflammation of that organ, excited by some of the ordinary intestinal flora. The speaker said that he believed that the ordinary pyogenic cocci were probably the primary factors, and the colon bacilli played a secondary part. Any alteration in the biliary ducts would often result in an ascending inflammation and an infection with the colon bacillus. His own experiments had shown the colon bacillus in about twenty-five per cent. of the gall stones examined. Adami had suggested that the colon bacillus might be an important factor in certain forms of cirrhosis of the liver, but this theory still lacked confirmation. The colon bacillus readily gained access to the kidneys and the bladder, and was apparently important in the causation of infectious nephritis. All observers were agreed as to its being a very common organism in cystitis, and his own ex-

perience seemed to indicate that it was more common in women than in men. The relationship of the colon bacillus to urinary fever had often been suggested. A few cases were on record in which respiratory affections had been associated with the colon bacillus. Practically all the diseases of the nervous system associated with this micro-organism were meningeal affections, which showed nothing different from that observed when the ordinary pus-forming organisms were present. The colon bacillus had been found in some cases of suppurative diseases of the nasal sinuses, and in three cases of purulent otitis. The organism was present in numerous localized suppurative processes. On the whole, the rôle of the colon bacillus might fairly be said to be quite secondary in character.

The Rôle of the Colon Bacillus as a Causative Factor in Inflammation of the Bladder.—Dr. S. Alexander discussed this part of the subject. He thought too much attention had been given of late to the pathogenic bacteria, and too little to the other causes. It could not be denied that the colon bacillus was frequently present in purulent urine, but it was generally of very moderate virulence. After referring at length to the controversy which had been waged between the schools on the question of the bacteriology of cystitis, the speaker came to the conclusion that bacteriology had added almost nothing to our knowledge of the genito-urinary diseases except the principles of antiseptic and aseptic surgery. A careful study of the published writings seemed to indicate that the colon bacillus was rarely found in cases of cystitis, except when the urine was acid. The colon bacillus seemed to be the cause of a certain number of cases of cystitis, but we could not assert that it was the most prominent cause. What we needed most in future research in this field were an accurate record of the clinical features of cases of cystitis, and the separation of the two sexes in addition to exact bacteriological work.

Dr. W. H. Park emphasized the statement that the colon bacillus was often given too much prominence in connection with disease processes. This was often because this bacillus grew so easily on all sorts of culture media, and overgrew all the other varieties. In his opinion, the colon bacillus was not, under ordinary conditions, pathogenic, but if because of anæmia or trauma or something of the kind the resistance of the tissues was decreased, the pathogenic action of the colon bacillus became apparent. There was little ground for hope that even in the future we would be able to get an agglutinating serum test for the colon bacillus or a method of serum therapy with which to combat the action of this organism.

Dr. Lartigau, in closing, said that he felt sure that the colon bacillus had been given too great prominence in all the infections, particularly in gastro-intestinal disorders.

President of Lunacy Commission.—On motion of Dr. C. L. Dana, the Academy of Medicine unanimously adopted the following resolution:

Resolved, That the New York Academy of Medicine is opposed to the repeal of the existing law which requires the president of the Commission in Lunacy to have had five years' experience in the treatment of the insane, and condemns any clause which would do away with this restriction.

SECTION ON SURGERY.

Stated Meeting, February 11, 1901.

John B. Walker, M.D., Chairman.

Radical Cure of Inguinal Hernia in a Child Two Weeks Old.—Dr. John F. Erdmann said that a child thirteen days old had been brought to him by Dr. Harry L. Purdy, with an irreducible strangulated inguinal hernia. He had operated immediately, relieving the strangulation and effecting a radical cure at the same time. The wound had healed by primary union, and the child's recovery had been rapid and uneventful.

Operation for Inguinal Hernia in a Diabetic Subject.—Dr. Arthur L. Fisk presented a youth of seventeen who had come to him one year ago seeking relief from an inguinal hernia. There had been at the time two per cent. of sugar in his urine, and this had continued ever since then; but recovery from the operation had been uncomplicated, and the subject's general condition had remained good.

Wiring of a Fractured Patella.—Dr. Fisk also presented a man who had fractured his patella by a fall on shipboard in 1868. The fracture had been treated at that time by the use of Malgaigne's hooks. Recently the patient had sustained another fracture of this patella, and accordingly, on December 24, 1900, Dr. Fisk had operated. He had found the old fracture, and also a rupture of the lateral ligament. He had cut out the fibrous union between the two sections of the patella, and had wired the fragments with silver wire. Since that time the limb had been kept up in a plaster cast. At present there was slight movement only, as he had not been anxious to have the limb used much as yet.

Chronic Intussusception; Resection and Recovery.—Dr. H. Lilienthal presented a man thirty years old, who had been referred to him by Dr. Morris Manges on November 6th. The patient had been perfectly well up to three months previously. After a severe exertion, he had drunk cold beer, and this had been followed by severe cramps in the region of the umbilicus, and these had persisted for several days, and had been associated with vomiting. After a few days the vomiting had been succeeded by diarrhœa and rapid emaciation. On dilating the colon with air, a mass, which had been observed over the colon, seemed to recede to the right side. On palpation, the mass would slip up beneath the ribs. On November 10th an operation had revealed the presence of a large intussusception, which was absolutely irreducible. He had incised it, pulled out the intussusceptum, and united the parts by Maunsell's suture. No Lembert's sutures were used externally. All drainage had been removed in a few days, and on the ninth day the bowels had been moved. The specimen was also presented.

Strangulated Hernia in a Child Eight Days Old; Successful Operation.—Dr. Lilienthal also presented an infant of a few months, whom he had first seen on July 1, 1900, in the practice of Dr. H. Heiman. At that time it was only eight days old. Since birth there had been present a hernia, and this had now become strangulated. At the operation he had found the ascending colon, the sigmoid, and the appendix, with a great deal of the small intestine. The canal was slit up and the hernia reduced with difficulty. Recovery had been very rapid, the parts having been practically healed at the first dressing, six days after operation. A hasty search through the literature led him to believe that this was the youngest child that had ever been successfully operated upon for strangulated hernia.

Dr. John B. Walker said that he had never seen a child under two weeks old in whom it had been necessary to resort to operation, because in all such cases that he had seen, suspension and taxis had succeeded in reducing the strangulation of the hernia.

A Cause of Strangulation in Infantile Hernia.—Dr. A. V. Moschcowitz said that last summer he had been called to see a case of strangulated hernia occur-

ring in a child of four months. Strangulation had lasted for four hours, and reduction could not be effected by taxis. It had been operated upon successfully. Another child had been seen by him three months after its birth. It had been born at the seventh month, and at that time, he had been credibly informed, it had weighed only one pound and a half, and had measured nine inches and a half in length. At the time of operation it had weighed five pounds. When brought to him, there had been a strangulated hernia, upon which he had immediately operated. The child had recovered well from the operation, but had subsequently developed pneumonia and mastoid disease, and although operated upon for the latter, it was now rapidly convalescing. He had found in these cases evidence of an unsuccessful attempt on the part of nature to close the tunica vaginalis. This had resulted in the formation of a constricting ring, and it was here that the hernia had become strangulated.

Dr. Robert T. Morris said that he had at present under his care a child in whom there was a similar ring, but he had supposed up to this time that this was a secondary formation. He was inclined, however, to accept the explanation just given.

Dr. Walker said that in some works on hernia this variety had been described as the encysted form.

Operations on Diabetics.—Dr. Morris said, regarding operating on diabetics, that the tissues were dry because the sugar in the blood was hygroscopic, and withdrew fluid from the tissue cells. It was this, he believed, which constituted the danger of operating in cases of diabetes. If the quantity of sugar were so small that its hygroscopic action was not sufficient to cause undue dryness of the tissue cells, and so interfere with the reparative process, an operation could be undertaken with safety.

Dr. Lilienthal said that while this was undoubtedly one danger, another and, he thought, a more important one, was the fact that the presence of the sugar afforded a medium favorable for the development of bacteria. Dr. E. Libman had shown that the addition of even a minute portion of sugar to culture media caused a striking change in the bacterial growth.

Dr. Fisk said that a search through the literature seemed to indicate that the mere presence of sugar was not to be considered a contraindication to operation, though operations in such cases must be carried out under the strictest antiseptic precautions.

Dr. Morris, referring to Dr. Fisk's case of fractured patella, said that in his last case he had used chromic catgut with good result. He had had to remove the silver wire in two or three cases because of the amount of irritation induced by the silver wire just beneath the skin. It seemed to him that in recent cases the chief reason for non-union was that the capsule was apt to be folded over the face of the lower fragment, and became adherent in this position. If this interposed tissue were removed it was not necessary to bring the fragments into close apposition.

Dr. Erdmann said that in the last case upon which he had done the open operation, he had used ordinary No. 2 catgut, and had obtained a perfect result. In a case of multiple fracture presented some months ago, he had simply stitched the capsule with ordinary catgut, and had obtained an excellent result.

Dr. John Rogers said that he had found it difficult to understand why silver wire should be used to hold bones together. The idea seemed to be that it was especially suitable to secure their close apposition, but while this was true, he knew from an unfortunate experience that the parts might be very closely apposed and fastened with silver wire, and yet in a short time the wire would cut through the bone.

Dr. Lilienthal remarked that he had used silkworm gut in two cases, with good result.

Dr. Fred. Kammerer said that he was not in favor of using silkworm gut, because he had found it especially irritating when employed as a buried suture. He thought catgut sutures were preferable to silver wire for uniting bone, and he had often made use of them for this purpose.

Dr. George E. Brewer said that the only object of having any suture at all was to keep the parts in place until union had begun, or, perhaps, until a plaster dressing could be applied. In the last two cases of fracture of the patella he had made use of the chromicized catgut and with complete satisfaction.

Dr. Walker said that his own preference was for a fine strand of kangaroo tendon, as it was a common experience that the silver wire must be subsequently removed.

Dr. Fisk said that he had been in no hurry to take off the splint in the case presented, because authorities generally recommended that it should be kept on for six weeks, and because the man had had no sense of security until very recently. In his cases of recent fracture of the patella, he had commonly made use of absorbable sutures, but this being an old fracture, requiring resection of the bones, the tension had seemed too great for the use of catgut, and hence he had employed silver wire.

Experience with Tracheotomy.—Dr. John Rogers read a paper with this title, in which he reported seven remarkable cases. In this series were four laryngotomies and eleven tracheotomies, without a death which could be ascribed to the operation. Most of his cases had suffered division of the cricoid cartilage, and experience seemed to show that this led almost invariably to bad cicatricial contraction. Laryngotomy, except for tumor, was absolutely useless. The use of ether had proved disastrous in tracheotomy cases; chloroform should be selected for this operation if any anæsthetic were required. With a low tracheotomy there was risk of wounding some of the large veins at the upper border of the sternum. Death from asphyxia might occur before the bleeding could be controlled. If the stenosis were not chronic, and a careful section were practicable, the low operation was to be preferred, but in cicatricial chronic stenosis the low operation was very troublesome. For emergencies and for chronic stenosis the high operation was safer and better. It was not always possible instantly to locate the exact seat of obstruction, but if a short tube did not give relief, a longer one should be tried.

Dr. W. K. Simpson said that in cases of chronic stenosis he thought intubation should be the operation of choice, as tracheotomy must always be looked upon as the more dangerous procedure. Experience had pointed out that if the nature of the obstruction were not known tracheotomy should be done, or one should be prepared to do it immediately after intubation. Tracheotomy should always be done with the idea of doing intubation very shortly; hence the high tracheotomy was distinctly preferable to the low operation. The longer the tracheotomy tube remained *in situ* the greater the difficulty of reaching the larynx with the intubation tube. He preferred the rubber tube because it did not become coated with calcareous matter. Dr. Rogers should receive the thanks of the profession for the modified tube he had devised. The "elbow" on this tube effectually prevented the tube from being coughed out.

Dr. Emil Mayer reported a case in which the tip of an atomizer had been thought to have been swallowed by a child. Eight days later it had been discovered in the larynx. The introduction of a probe into the larynx had revealed at first no foreign body, and from the history he had felt disposed to believe that the stenosis was diphtheritic. Forty-eight hours

later, on attempting to introduce an intubation tube, the stenosis had become extreme, so he had administered chloroform, preparatory to doing a tracheotomy. Before this operation could be begun, respiration ceased, and although the operation was hastily performed and the foreign body removed, the child could not be resuscitated. Dr. Mayer had always felt disposed to think that the chloroform had killed this child. Another case which he reported was that of a man who had been shot in the forehead at the battle of El Caney. An incorrect diagnosis had been made at one of our large hospitals, in spite of the laryngeal stenosis; but on coming under his observation he had been led to look for the foreign body, because of a punched-out hole which could be plainly seen in one side of the curtain of the palate. This man had ultimately been relieved by treatment with Schroetter's tubes. It was surprising that, in this country, so little post-typhoid stenosis was observed. This was probably to be explained by the fact that specific diseases in general were not so severe in their ravages in America as in some other countries.

Dr. Kammerer said that he would not think of using ether as the anæsthetic for a tracheotomy. He had done this operation two hundred and eighty times, for the most part in cases of diphtheria, and he had always found that the moment chloroform was administered the asphyxia was greatly increased. One of the most important things to remember in doing a tracheotomy was to perform it without undue haste. This was especially true in the case of children, and even if breathing should cease it could almost always be restored by artificial respiration. His experience had been that the inferior operation was much easier than the high operation. He had always found that if the double cannula were worn for any length of time, granulations would form and cause trouble on attempting to remove the cannula. It was strange that so few of those who had been subjected to tracheotomy in infancy lived beyond the age of twenty years. The fact could not be denied, but it was not so easy of explanation.

Tracheotomy a Dangerous Operation.—Dr. Brewer said that at one time he had seen a great many tracheotomies, for the most part for diphtheria, done at the Boston City Hospital. On account of the strong feeling there against chloroform, nearly all of these children had been given ether, and he recalled very vividly the awful struggles under the ether. Finally they had come to do the operation in many instances without any anæsthetic, and although it was certainly a very painful procedure, he thought these children had suffered but little more than they would have done under ether. Since that time he had made use of chloroform, and had found it a great aid. He was of the opinion that all tracheotomies were dangerous, whether done for diphtheria or as a preliminary to some other operation. His experience had led him to dread septic pneumonia after all tracheotomies.

Dr. Francis J. Quinlan spoke of a case in which he had removed a double-headed screw-bolt by tracheotomy, and had immediately sutured the wound, though urgently advised by his colleagues against what they thought to be such a dangerous procedure. However, primary union had occurred, and recovery had been most satisfactory, the cosmetic effect being all that could be desired.

Dr. A. A. Berg spoke of the method of treating cases of marked cicatricial stenosis by the use of epitheliai grafts, rather than by continued tubage.

Dr. Rogers replied that this method of grafting could hardly prove effective in many of these cases, and it was without doubt quite dangerous. On the other hand, the wearing of an intubation tube would effect a cure.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 5, 1901.

Joseph Collins, M.D., President, in the Chair.

A Case of Locomotor Ataxia Trained by the Fraenkel Method.—Dr. A. Wiener presented this man. He had been under this system of training for about one year, and while ataxia was still present, he had been very greatly improved, and was now able to go about even at night unaided. There had been no other treatment for the tabes.

Sarcoma of the Brain.—Dr. A. Wiener also presented a pathological specimen from a person seventeen years of age, who had first come to him about November 1, 1898. There was an absolutely negative history of alcoholism or syphilis. About two years before this time the patient had suffered from a severe fright, and almost immediately thereafter had had a severe convulsion. Nothing further had been noticed until the summer of 1898, when she had suddenly developed a difficulty of speech, with right facial palsy. She had suffered from bad headaches frequently, for three months previously. On coming under observation there had been excruciating pain over the occipital region, complete deafness in the right ear, and a bulging of the tympanic membrane. The right sterno-mastoid muscle had been in a state of constant contraction, and there had been a double optic neuritis, most marked on the right side. The voice was hoarse. Neither the upper nor the lower extremities had suffered any loss of power. There was no swaying when the eyes were closed, nor was there any bladder trouble. Her temperature was 100° F. The seventh, eighth, ninth, tenth, eleventh, and twelfth nerves were affected on the right side, and the sixth nerve on the other side. On November 8th a slight ptosis had been noticed, and the twelfth-nerve palsy had become more marked. On November 28th there had been vomiting, vertigo, and an increase in the ptosis of the left eye. On December 8th there had been complete third-nerve palsy on the left side, and the headache had been very severe. A tumor of the brain having been diagnosticated, the patient had been sent to the Mount Sinai Hospital. A mass had developed behind the ear, and on aspiration of this it had been found that the case was one of congenital sarcoma. On January 11, 1899, the third-nerve palsy had entirely disappeared on the left side, and the swelling behind the ear had grown larger. On January 21st the patient had suddenly become confused, and blind in both eyes. In April it had been decided to open the mass to relieve the pain. By June 30th the patient had been up and around again. In October there had been a complete brachial-plexus palsy on the right side. The tumor had kept on growing until it was almost the size of the patient's head. The patient had died on February 2, 1901, and an autopsy had been performed. The whole tumor had been found below and outside of the brain. In front was a large giant-cell sarcoma which had completely destroyed the sphenoid bone. At the back the tumor had destroyed the occipital bone. The brain was exhibited, and it showed that only the pons had suffered pressure. The tumor had apparently started in the mastoid portion of the temporal bone.

Tendon Transplantation for Deformity of the Hand.—Dr. W. R. Townsend presented a case of this kind, which had been exhibited to the society about one year ago. It was a case of infantile cerebral palsy. Instruments had been used at the time of birth, but no damage had apparently been done to the exterior of the skull. The boy had never been able to use the right hand, and it was a typical "claw hand" when he came under observation at the age of fifteen years.

On December 21, 1899, an incision had been made over the wrist, exposing the tendons. The flexor carpi radialis, the flexor carpi ulnaris, and the palmaris longus were divided just above the annular ligament. The hand was then turned over and an incision made on the dorsum of the wrist, and the extensor communis digitorum exposed. A dissection having been made through the interosseous space, the extensor tendon was pushed through, and being too long, was doubled upon itself. It was then attached to the tendons previously mentioned. The union of the tendons had been satisfactory and permanent. The tendons had not shown any tendency to unite to the surrounding tissues. The patient was now able to write fairly well, whereas formerly he could not even grasp a pen.

Dr. B. Sachs said that he had been deeply interested in this subject, and it was certainly the best procedure that had been suggested for these cases of contracture, whether of spinal or cerebral origin. The problem was to split the tendons of the over-acting muscles and unite them to the tendons of the under-acting muscles, and so restore the equilibrium of power. It had been found prudent not to allow the patient to exercise much, or to use electricity, until the tendinous union had become very firm. It was unfortunate that this boy was not able to extend his fingers, yet he had secured good extension of the wrist. In spite of the tendon transplantation, the boy experienced no difficulty in producing flexion when he desired to do so.

Dr. Schlapp remarked that it seemed to him that the boy's hand was decidedly larger now than when he had seen the case a few months ago.

Dr. Creighton presented a young woman, of neurotic temperament, who four years ago had had hysteria and typical attacks of grand mal. One year ago she had had the grippe followed by pneumonia, and this had been succeeded by headaches, aching spine, and numbness in the left side. There were severe contractures in the left arm. A small, painful tumor had appeared in the left palm, and had been removed by the family physician, under cocaine. It had returned, and had been again removed. A galvanic current of 10 M.A. had brought out a slight redness on the palm. Three days before menstruation a large red spot had appeared on the back of the forearm, and soon afterward several similar spots had made their appearance on the arm. A few days before the next menstruation these spots had returned, and in addition, a number of large blotches on the left shoulder and on that side of the neck. The whole side was very hyperæsthetic. There was slight narrowing of the visual field, and there was left-sided sweating. The speaker said that the case was very similar to one recently reported from Erb's clinic.

Dr. Joseph Fraenkel asked whether there had been a history of malaria, and whether the case might not be looked upon as one of morphœa.

Dr. Creighton replied that there was no history of malaria, and the family physician had stated that the tumor which he had removed, grew on the nerve. The microscopical examination had been made at the laboratory of the Presbyterian Hospital, and the report had been that there was a slight round-cell infiltration only, no nerve degeneration having been found. The thyroid gland was not enlarged.

Dr. C. L. Dana said that he had seen cases presenting just this appearance, but entirely free from hysteria.

Dr. W. B. Noyes said that four or five skin lesions were closely associated with nervous troubles. Herpes zoster, erythema multiforme, Raynaud's disease, all were distinctly related to the nervous system, yet it was very difficult to state the exact relation. It had occurred to him that the element of suggestion, regarding the connection with the nerve, might be responsible for some of the phenomena present.

Dr. E. D. Fisher said that this could not be properly described as simple hysteria, or as the result of mere suggestion. The eruption was not characteristic of an hysterical state.

Dr. M. G. Schlapp said that these cases had been described before; they had been brought on by suggestion. In this case an injection had been given in the arm, and shortly afterward this dermatitis had first appeared. The eruption was not characteristic of any particular skin lesion, but it closely resembled cases that had been described as hysterical skin manifestations. In typical zoster there was frequently a degeneration of the nerve fibre itself.

Dr. Sachs said that the case was a very unusual one, and he did not regard it as belonging to the class of hysterical hyperæmia. It was certainly a distinct form of skin neurosis. The closest resemblance in the anatomical distribution was to herpes.

Dr. Joseph Collins said that if the girl should develop a pneumonia, he would not be willing to call it an hysterical pneumonia; neither was he willing to call this an hysterical skin disease. He was inclined to think it was closely related to morphœa.

Dr. Creighton said that a case had been reported very recently in which the gangrenous form had ultimately developed. This case had been described as hysterical. Dr. J. C. Johnston, the dermatologist, had seen this patient, and had looked upon the case as hysterical.

Paralysis of the Spinal Accessory.—Dr. Pearce Bailey read this paper. He said that the chief interest in this nerve was surgical. Within the past year two instances of accidental section of the nerve had come to his notice. In most cases the paralysis which resulted from section was not particularly disabling, but such had not been the case in the instance referred to. When the sterno-mastoid was completely paralyzed, the freedom of movement of the head was interfered with, but not totally abolished. In the two cases referred to, the disability had been unusually great, and had led him to study more carefully the nerve supply. The nerve was now regarded as a spinal nerve, pure and simple. The spinal portion of the nerve, represented by the external branch, sprang from the upper five segments of the cord. Paralysis of the nerve presented a varying symptomatology, according to the site of the lesion. An injury outside of the skull, to cause symptoms referable to both branches, must be situated directly at the base of the skull. The extracranial lesions of the spinal accessory were confined to the external branch, and were nearly always traumatic. Neuritis in this nerve was rare. A case was cited, to illustrate the possible traumatic origin of spinal accessory palsy, from injury with a blunt instrument. In two other cases reported, the paralysis had been directly the result of an operation. In the second case the resulting incapacity had been so great that the right arm had been rendered practically useless for any heavy work. Neurorrhaphy had been performed about six weeks after the operation at which the nerve had been injured, and the ends of the divided nerve had been found separated over one inch. The improvement in motor power had been slow. A reference to the literature showed conflicting views regarding the nerve supply. Dr. Bailey said that the spinal centre between the first and fifth cervical segments of the cord was fixed and constant, but occasionally all the axons passed to the muscle by the spinal accessory. Under these circumstances, the motor impulses reached the trapezius through the spinal accessory and, hence, section of it meant total palsy.

Dr. W. M. Leszynsky said that he had seen a patient two months ago who had been operated upon for torticollis. Over one inch of the spinal accessory nerve had been removed on the left side without relief,

and the function of the muscle had remained perfectly normal. He had seen over an inch of the other spinal accessory nerve removed subsequently, yet the muscle had not been affected at all; hence he had held that it was useless in these cases of spasm to operate upon the spinal accessory nerve.

Dr. J. Arthur Booth said that he had had a case of spasmodic torticollis operated upon by section of the spinal accessory nerve. A little more than one inch had been excised, and the sterno-mastoid and part of the trapezius had been paralyzed as a result.

Malaria.—

℞ Methylene blue..... gr. ij.–iij.
Quinin. sulphat..... gr. ij.
Ferri carbonat..... gr. i
Ac. arsenosi..... gr. $\frac{1}{50}$
M. ft. caps. No. i. S. In acute fevers one three times daily; in chronic forms one every four to six hours.

—Dunn.

Sycosis.—

℞ Creosote..... ♏ xv.
Ammoniated mercury..... gr. xv.
Oil eucalyptus..... ♏ x.
Zinc ointment..... ʒ i.
M. S. Rub into the surface night and morning. After a time use tar soap.

Internally:

℞ Arsenious acid..... gr. $\frac{1}{50}$
Iron pyrophosphate..... gr. i.
Ext. nux vomica..... gr. $\frac{1}{10}$
M. S. One such pill after meals and at bedtime.

—Shoemaker.

Chronic Arteritis.—

℞ Hydrochlorate of hydrastinine..... 0.10 gm.
Iodide of sodium..... 2. "
Anisette of Bordeaux..... 100. "
Distilled water..... 200. "

About an ounce each morning, to be increased according to results obtained. Interrupt treatment one week in each month. Or—

℞ Hydrochlorate of hydrastinine..... 1 gm.
Sterilized water..... 10 c.c.
S. Inject from half a syringeful to a syringeful twice a day.

—Boix.

Acute Tonsillitis.—

℞ Quinin. sulph..... gr. xlviij.
Dilute sulphuric acid,
Tinct. aconite.....āā ♏ xlviij.
Syrup wild cherry..... ℥ i.
Water.....enough to make ℥ iij.
M. S. ʒ i. in water every four to six hours, for an adult.

Locally:

℞ Spts. chloroform..... ʒ iij.
Eucalyptol,
Glycerin.....āā ʒ i.
Tannic acid..... gr. ij.–v.
M. S. Apply with brush three times daily.

Influenza.—

℞ Acetanilid..... ʒ i.
Spir. vini rect..... q.s.
Tinct. gelsemii..... ʒ ss.
Syr. zingiberis.....q.s. ad ℥ ij.
M. S. Teaspoonful every two or three hours.

—*Medical Summary.*

Potassium bicarbonate, gr. xxx. in milk or water, every four hours, is almost a specific.—Harsherger.

In the respiratory form to relieve chest oppression and cough:

℞ Ammon. carb..... gr. v.–x.

in two ounces of milk.—Wilcox.

Influenza in Children.—

℞ Sodium benzoate,
Salol,
Acetanilid.....āā gr. iss.
Caffeine..... gr. $\frac{1}{4}$
S. One such powder every three hours to a child of six years.

—Sheffield.

Capillary Bronchitis.—

℞ Vini antimon.,
Spir. chloroformi.....āā ʒ iv.
Spir. ammon. arom..... ℥ i.
Liq. ammon. acet..... ℥ ij.
Aquæ.....ad ℥ viij.
M. S. Tablespoonful every hour.

—Whitla.

Tuberculous Laryngitis.—In the first stage place a dessertspoonful of the following in a pint of water kept slowly boiling and let the patient inhale:

℞ Tinct. canellæ,
Tinct. bellad.,
Tinct. opii.....āā 30
Tinct. eucalypti..... 100

In the second period lactic acid gives excellent results, but its application must be energetic and repeated.—Bommier.

When there is pain:

℞ Di-iodoform..... 8.
Hydrochl. cocainæ..... 0.08
Hydrochl. morphinæ..... 0.04
Give four to eight aspirations daily.

—Leduc.

For an insufflation or gargle:

℞ Cocain. hydrochl..... 1.
Morphin. hydrochl..... 0.80
Acid. phenic..... 1.
Antipyrin..... 4.
Glycerini puri,
Aq. menthæ pip.....āā 50.
Aq. destil..... 300.
M.

—Bommier.

Pruritus Ani.—A rectal injection of ergot, hydrastis, and carbolized oil is first given. If the skin is hard it is painted with a saturated solution of silver

nitrate every third day for three visits. Then every day citrine ointment is used and bound on with a cotton pad. The itching at night may be relieved by extremely hot water followed by black ointment or calomel salve, being careful not to scratch the skin. This daily routine is followed for six weeks, then at longer intervals for six months, never stopping in less time, but occasionally persisting longer.—L. H. ADLER.

Stimulant for Children.—Musk, five or ten minims of a ten-per-cent. tincture every half-hour until upward of a dozen doses have been taken if necessary.—JACOBI.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 23, 1901:

	Cases.	Deaths.
Tuberculosis	250	179
Typhoid fever	28	5
Scarlet fever	437	24
Measles	198	5
Diphtheria and croup	257	37
Smallpox	43	9

Professor Chiene on Enteric Fever in South Africa.—Professor Chiene, speaking recently in Edinburgh, gave some of his views with regard to the state of affairs from a medical and surgical standpoint in South Africa. He said, in part: "To a great extent in Kimberley, Bloemfontein and Kroonstadt, and almost entirely in Johannesberg and Pretoria, the sick and wounded were in hotels, churches, and halls, and if there was free ventilation and the rooms were large they made excellent hospitals, but tents and hospital huts were better than houses. The purification of buildings must be very thorough. Many South African friends expressed to me their fear for the coming year and they anticipate a great outbreak of enteric in the near future. This would be a very serious affair, looking to the flood of emigrants who would rush north whenever they got the chance. There should be no delay in sending out the best incinerators and compelling the authorities to burn the dejecta. Burying was common in Cape Colony, in the Orange River Colony, and the Transvaal. In the three large hospitals in Natal, Estcourt, Mooi River, and Howick the dejecta were burned. At Johannesberg all the Kaffirs who removed and burned the dejecta were in good health, and in a very short time the earth in the trenches in which the burial had taken place resumed its normal appearance. Still, burning was infinitely preferable. There should certainly be incinerators at all the railway stations to burn the dejecta from the hospital trains. Phlebitis of the common femoral vein was a frequent complication in enteric delaying recovery, but not causing a fatal issue. Patients with typhoid died from exhaustion or hemorrhage, rarely from perforation. There was much difference of opinion as to the merits of typhoid inoculation. It would be some time before the results could be tabulated; the medical sheets of the soldiers did not accompany them and no definite data could be obtained, more especially from those who were admitted into hospital in a moribund condition."—*British Medical Journal.*

Sir Dyce Duckworth on the Drug-Taking Habit.—Sir Dyce Duckworth, in a recent lecture on mental disorders dependent on toxæmia, refers to the increasing habit of drug-taking in the following plain-spoken terms: "We have to note the mental aberrations due to the vicious use of agents, such as morphine, chloral hydrate, paraldehyde, ether, and cocaine, and to remark concerning all of them that their abuse increases in frequency in what we are pleased to call the advance of knowledge and civilization. That our profession is in part to blame for some of this mischief I entertain little doubt. The resort to these and similar agents under conditions which hardly justify their employment, and which might often be met by other and simpler therapeutic measures, has often led to habits of secret intoxication by patients who indulge in them. The frequent handing over of hypodermic syringes and these poisons to nurses is also to be blamed. The too ready sale of such agents by pharmacists and other tradesmen is a matter so serious that it now calls for some special legislation to restrict it. The danger lies in the special seduction of such agents for women and persons with unstable brains, and no cure and precaution can be too great in prescribing for them. We are all familiar with the disastrous results of yielding to the cravings for hypnotics and sedatives, and know too well our impotency to do any permanent good in the great majority of such cases. We certainly find that the average patient is singularly intolerant of any pain in these days, and that he clamors for relief at any price. Our forefathers had to suffer more than we do, and I am not sure that they were always the worse for it. They certainly escaped the modern terrors of morphinism, chloralism, and cocainism, and the women of those days bravely endured their catamenial discomforts without recourse to stupefiants. I think a good deal of plainer living and higher thinking would avail much to abolish the too common resort to anodynes which unhappily now prevails so largely in several strata of society, both in this and other countries."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended February 23, 1901:

		Cases.	Deaths.

THE PERIOD OF INCUBATION OF YELLOW FEVER: A STUDY FROM UNPUBLISHED OBSERVATIONS.[1]

BY HENRY R. CARTER, M.D.,

SURGEON, UNITED STATES MARINE-HOSPITAL SERVICE.

FOR a vessel to receive free pratique at a quarantine station the quarantine officer must be satisfied of two things:

(1) That the vessel and cargo, including baggage, are free from the infection of a quarantinable disease.

(2) That none of her personnel, passengers, or crew have such disease, either already developed or in the stage of incubation.

For the first part, if the vessel be judged infected, the officer disinfects; for the second, the sick, if any, are removed, and those who are adjudged liable to have the disease in its incubative stage are detained under observation to cover the period of incubation of the disease in question, counting from the last exposure. Since the time of detention of those adjudged exposed to infection depends on the period of incubation of the disease to which they have been exposed, it is obvious that a knowledge of the period of incubation of the quarantinable diseases is a matter of first importance in maritime quarantine. It is to set forth some data not hitherto presented on the period of incubation of yellow fever that this paper is submitted. First, let me say that in the systematic treatises on yellow fever there are less certain definite data on this subject than its importance demands. True, all give a period of incubation within limits, generally "from one to fourteen days"; but do not in general give the data on which this statement is based.

Of course there are exceptions, and some very valuable data are found in some of the works alluded to; still the number of yellow-fever cases in which the period of incubation has been positively ascertained and definitely and reliably recorded is small.

There are three classes of observations of value in determining the period of incubation of yellow fever:

Class I. A person goes from a clean into an infected environment and remains there more or less continuously until he develops the fever. The time from his entrance into the infected locality to the development of the fever is named by a number of writers as the period of incubation of the case in question. Thus Bemiss writes:

"The periods of time which may intervene between exposure to yellow-fever poison and attacks of the disease are extremely variable. The shortest period of incubation which has come under my observation was about twenty hours. In three cases in which I was able to fix the hours of the first exposure with precision, attacks followed in 72 hours, 83 hours, and 101 hours respectively. Of 55 unacclimated physicians who exposed themselves at Memphis during the epidemic of 1878, 54 suffered attacks of yellow fever. In these cases the incubation varied from 1 to 25 days, the average duration being 10 days. These physicians all remained steadfastly at their posts of duty; consequently the attack which occurred on the 25th day was postponed for that length of time, during constant exposure in a locality most intensely infected."

And so say not a few of the older writers—Rush, Dutrolan, Blair, and others.

This deduction, as Wilkinson has shown, is unwarranted. A patient (take for example one of Bemiss') is first exposed one hundred and one hours before development of the fever, but he is continuously exposed up to that time, and we have no reason to claim that the first exposure was the one at which he received infection. It may have been received at any moment from the first exposure up to the development of the fever. These observations do give, however, the maximum limit of the incubation in each case. Thus, in the three cases given by Bemiss, we can say that the period of incubation was not greater than seventy-two, eighty-three, and one hundred and one hours respectively. It might have been anything less than that. Similarly for the cases quoted as occurring in Memphis. The case developing twenty-five days after first exposure had a period of incubation not more than twenty-five days; it may have been one day. It is fair to say that in a virulently infected place, a place one visit to which usually results in an attack of yellow fever, the first exposure for a considerable proportion of people would be the infecting exposure, and that this maximum limit would be the true period of incubation. Still, for a particular case we cannot claim this. If we have very many such cases, it is obvious that some of them will give the inferior limit of the period of incubation. Beyond that, nothing can be determined from this class of observations, and for maritime quarantine the inferior limit of the period of incubation is comparatively of no great importance.

Class II. A person goes from an infected environment into a clean one and there remains until the development of the fever.

We have instances of this kind in the personnel of infected vessels at quarantine, moved to clean quarters or having their quarters made clean; in people leaving an infected town for a detention camp or for any other place known to be clean, etc. The vessels at quarantine and the detention camp offer peculiar advantages, because there should be no question of infection by anything carried from the infected place (vessel or town), and from the frequent inspection the exact date (usually hour) of the attack of sickness is known. In using these observations for the determination of the period of incubation, we must assure ourselves that what is given as the date of last exposure to infection is this in truth, and not count time on a possibly infected vessel, or while the patient is exposed to anything capable of conveying infection, as "time since last exposure." Most of the very long periods of incubation reported have been due to a disregard of this principle. Thus a case of yellow fever developing at a quarantine station aboard a vessel sixteen days out from Havana is reported as showing a "period of incubation of sixteen days, longer than has generally been believed." Although the case may well have

[1] Read before the Third Pan-American Medical Congress, held in Havana, February 4, 5, 6, and 7, 1901.

been contracted aboard the vessel, yet it is generally improper to accuse the clothing worn by the individual, if worn some time in the open air and sunlight, as a source of infection to the wearer, the evidence being overwhelming that clothing thus worn does not convey the infection of yellow fever save in very exceptional circumstances. The only cases ever reported as thus conveyed have been from the clothing of those who had been in intimate contact with the sick, nursing, etc. And even these cases are, in the writer's opinion, not more than very probable.

Yet we have no more right to say that the time from the leaving of the infected environment to the development of fever is the period of incubation of that case than we had to make the converse statement for one going from a clean to an infected environment, under Class I. These people have been exposed to infection a more or less extended time, and to claim that the last possible exposure, the date of leaving the infected environment, was the infecting exposure, is no more allowable than to claim that the first exposure of those going from a clean into an infected environment was the infecting exposure.

The conditions are exactly the converse of those occurring under Class I. Just as with one going from clean to infected environment the period of incubation is not greater than the time between his coming into an infected environment and the date of the development of the fever, so with one going from infected to clean environments, the period of incubation is not less than the time between his coming into a clean environment and the date of the development of the fever. Thus a case occurred at the Louisiana quarantine station aboard the steamship *William Clift* from Vera Cruz, forty hours after the completion of disinfection (Wilkinson). The fever may have been contracted aboard, an indefinite time before the disinfection, and even about six days before the vessel left Vera Cruz. Of a case occurring in the detention camp at Camp Perry three days after admission, we say that its incubation period was not less than three days; the fever may have been contracted an indefinite time before the patient left Jacksonville. If we have a large number of such cases some of the patients will have contracted the disease at the last exposure, and the period since that time will give the true time of incubation. Again, for vessels which have gone long periods without any sickness aboard and are a long time from the port of departure, if yellow fever develops aboard such a vessel soon after disinfection, it is, in general, reasonable to ascribe its contraction to the period of disinfection, on account of the general overhauling of the ship—whether from the overhauling of dunnage or visiting parts of the vessel (hold, etc.) for the purpose of cleaning, which were not visited en route. In these cases the time from the disinfection to the development of the fever is probably the true time of incubation of the case. Only for wooden ships, the cleaning of which may take a day or several days prior to the disinfection, it is more correct to say that the period of incubation is not greater than the time from the beginning of the cleaning to the development of the fever, and not less than the time from the completion of the disinfection to the development of the fever. For example. the British ship *Curlew* left Rio Janeiro May 19, 1890, having had no sickness in port, *en route*, or on arrival; the ship was cleaned July 22d to 23d, and disinfection completed July 25th. One case developed among the crew on July 27th.

Now, this vessel had a crew of about eighteen non-immunes aboard her, with no sickness from May 19th to July 25th, sixty-eight days. It seemed fair to believe that this condition would have continued indefinitely if the condition of life aboard the vessel had remained unchanged. It seems reasonable, then, to ascribe the contraction of this case to the period from July 22d to 25th, with an incubation of between two and five days. Nevertheless the writer has seen one case on a wooden ship, in which a first case of yellow fever developed at sea, without the ship having been cleaned, thirty-eight days out from Rio, so that the above deduction though reasonable is not absolute.

Class III. Cases in which there is only a single short exposure to infection, followed by development of yellow fever. In these the person living in a clean environment goes into an infected one, stays only a short time, and returns to a clean environment where he remains and develops yellow fever.

If we can assure ourselves that nothing capable of carrying infection accompanied the patient from the infected environment (*i.e.*, that the clean environment is in truth clean), we have a definite, single exposure, and the time from that exposure to the development of the fever is the period of incubation of that case.

Unfortunately the cases of this kind hitherto recorded, on which we can rely because the details are given with such fulness, clearness, and definiteness as to be fully trusted, may be counted on less than the fingers of one hand.

Class I. A large number of cases of persons leaving clean environment for an infected one, and there developing yellow fever, are on record. On this account, and because the only finding possible from this class of observations—the minimum period of incubation—the writer has made no systematic attempt to collect this class of cases. He did, however, in 1898 collect all such cases as occurred at the Gray House at Orwood, Miss., which are given below. All except the last one, D. C., were from the writer's own notes. It was unquestionably a virulently infected place. Of forty-six non-immunes who lived in or visited it after August 21st, all developed yellow fever, although some of them had other exposures as well, and two most probably contracted the fever elsewhere.

Mrs. M. C. K—— came to Gray House to nurse, August 28th, at 1 A.M. She sickened there August 31st, 2 A.M. Incubation not more than three days.

Mrs. M. McC—— came to Gray House to nurse, August 27th, 2 P.M. She sickened September 1st, 9 A.M. Incubation not more than four and three-quarter days.

Dr. W. T. M—— in Gray House August 29th, afternoon; went back on the 30th, and remained until taken sick, September 3d, 2 P.M. Incubation not more than four and one-half days.

P. D—— (colored) went to Gray House to nurse, September 27th. He sickened October 3d, at 2 P.M. Incubation not more than seven days.

G. W. S—— at Gray House from August 29th, 10 A.M. He sickened September 2d, 3 P.M. Incubation not over three and three-quarter days.

P. S—— at Gray House August 25th to 29th, when he sickened at 3 P.M. Incubation not more than four days.

D. C—— (colored) at Gray House, for outdoor work, from August 25th to September 20th, when he sickened. Incubation not more than twenty-six days.

The shortest period of incubation here given is three days, the same (seventy-two hours) as given by Bemiss for those cases of which he has "definite knowledge" of the first exposure; but there are many observations of record which give the minimum period as less—some even less than twenty-four hours.

It will be observed (Class III., pages 365, 366) that except for the last case, which was about, rather than in, the house, the periods given for the maximum limit of the periods of incubation are not essentially different from those which are given as the true periods (obtained from a single exposure) for this house. It would seem, then, that those living in this house after it became infected, the whites at any rate, generally

contracted the fever very soon after entering it, and that in cases of those in which the incubation is given between limits—as P. S. and some others of Class II. —it is probable that the higher limits of the period of incubation are more nearly correct than the lower ones.

Class II. On the other hand, the cases under Class II., those of persons who after a more or less continuous exposure in an infected environment move into a clean environment, and there develop yellow fever, merit consideration in detail, and no pains have been spared to observe and record suitable cases.

It may seem remarkable that the observations of this class have been so little used for determining the period of incubation of yellow fever. The data they supply are far more valuable practically than those from Class I., and are complementary thereto. Yet, save Wilkinson, who reported and thus used five cases from three vessels at the Louisiana quarantine station, I think no writer has availed himself of this material for the purpose in question.

It is only recently, however, that this class of data has become available. Detention camps began in 1888, and even at that time and after, the data from a number of quarantine stations would have been not acceptable on account of doubt of the efficiency of their disinfection.

The number of cases under this class which occurred at all the quarantine stations South was small. Thus the Mississippi River station of the State of Louisiana, far the largest, gave only five such cases in the sixteen years ending 1896. About the same showing is made by the United States refuge stations, which received all the vessels adjudged to be infected, from ports between New Orleans and Baltimore and some Texas ports.

As before stated, only those cases can be considered which we are sure are exposed to nothing capable of imparting infection after the time we count as the period of last exposure.

Class II. (A) From maritime quarantine stations. Here I will say that I have used only cases which occurred at stations where I believe good disinfection work was done, the officers in direct charge of the stations being all well known to me. I believe I have excluded some cases which should have been used; I do not believe I have used any which should have been excluded.

1. Steamship *William Clift* from Vera Cruz, arrived August 7, 1891, afternoon, with two cases of yellow fever aboard, attacked the 5th and 6th of August respectively; she was disinfected the same afternoon. Another case was found ill in the early forenoon of August 9th. Incubation not less than forty hours.

2. Steamship *Denia* from Havana, arrived in the forenoon of August 26, 1892. There was no record of sickness in port or *en route;* she was disinfected the same forenoon. Two men were attacked with yellow fever within eight hours after disinfection. Incubation not less than eight hours for both.

3. Steamship *Vesta* from Vera Cruz, arrived and was disinfected August 26, 1894, forenoon. On arrival she had one case of yellow fever, ill three days. One man was taken sick within two hours after completion of disinfection. A second man was found ill next morning, August 27th, within eighteen hours after the completion of disinfection. Period of incubation of first case not less than two hours. Period of incubation of second case not less than eighteen hours.

These three vessels are reported by C. P. Wilkinson, quarantine officer, State of Louisiana.

4. British ship *Curlew* from Rio Janeiro, with rock ballast, sixty-eight days out from Rio. No sickness was reported *en route*, in port, or on arrival. She was cleaned July 22 to July 23, 1890, and disinfection completed July 25th, in the afternoon. One case of yellow fever developed July 27th in the early morning, before day. Incubation not less than one and one-half days. The disease was probably contracted between August 22d and August 25th, *i.e.*, incubation between five days and one and one-half days. (Carter, United States quarantine officer, Chandeleur Island.)

5. British ship *Chippewa* from Rio Janeiro, with rock ballast, sixty-four days from Rio. No sickness was reported in port, *en route*, or on arrival. She was cleaned July 26th and July 27th, and disinfection completed July 28th. One man, the quartermaster, developed yellow fever July 29th at night. Incubation not less than one day. He probably contracted the disease between July 26th and 28th. Incubation three and one-half to one day. (Carter, United States quarantine officer, Chandeleur Island.)

6. American schooner *Eva Douglass*, with swept hold; four days from Havana (lay at Tallapiedra wharf) to Mullet Key quarantine station. Certainly she had three cases, probably four, in Havana. All were well *en route* and on arrival. She arrived August 3, 1892, and was disinfected August 4th. The captain developed yellow fever in the afternoon of August 5th. The mate and two seamen were found sick in the morning of the 7th (they had probably sickened the night before. H. R. C.) Incubation of captain not less than one day; of mate and seamen not less than two or two and one-half days. (J. Y. Porter, State health officer of Florida; and D. M. Echemendia, State quarantine officer, Tampa Bay quarantine.)

7. Schooner *Jno. R. Bergen* left Havana August 10th, arrived at Tortugas quarantine August 12th in early morning; in bluestone ballast, small amount. One man, sick in Havana, was left in hospital. Another man, the mate, attacked in Havana, was brought to Tortugas for care. The vessel was emptied, cleaned, and disinfection completed August 16th, late in the afternoon. One man, the engineer, developed yellow fever on the night of August 20th, when he woke up with a chill after he had turned in. Incubation not less than four days and two hours. This man was the only member of the crew who assisted in cleaning the rooms which were occupied by the engineer who died in Havana. (Carter, United States quarantine officer, the Dry Tortugas station.)

8. Schooner *Louis V. Place* left Havana August 25, 1894. She had no sickness in Havana, and arrived at Tortugas August 26th, with two cases of yellow fever who had sickened *en route*. The crew was removed ashore to clean quarters, with sterilized clothing and bedding, August 27th, just before noon. The vessel was cleaned and handled the same day, exclusively by quarantine employees. One case of yellow fever developed aboard her August 30th at 2 P.M., a sudden attack, "coup-de-barre." Period of incubation not less than a little over three days. This man, an Italian, had a very thick head of hair, to the washing of which, with bichloride solution, extra attention was paid. He ascribed his attack of fever to this washing. (Carter, United States quarantine officer, the Dry Tortugas station.)

9. Barge *Henry L. Gregg* moved over into the open bay, Trisconia, from Tallapiedra wharf, Havana, with a case of yellow fever just removed, August 13, 1899, and swept hold. She was disinfected August 13th to 16th, by the writer. One man developed yellow fever August 20th at night. He was well at inspection at 6 P.M. Incubation not less than four and one-half days. She was again disinfected and pratique for Havana given September 1st. No other cases occurred up to the time of her leaving port, September 9, 1899. (Carter, quarantine officer, Havana.)

10. Schooner *R. D. Spear* from New York to Key West, where she lay unloading during the epidemic of 1899. The crew was not allowed ashore, but the

captain went ashore every night. She left Key West September 15, 1899, and arrived at Mullet Key quarantine September 19th. Disinfection was completed September 20th, 4 P.M. The captain sickened and had a chill on September 24th at 2 A.M. Incubation not less than three days and ten hours. (D. M. Echemendia, quarantine officer, Tampa Bay quarantine, Florida board of health.)

Class II. (B) Cases under Class II. from detention camps. A detention camp will not be described further than to say that the persons entering one have first their hand baggage (containing at least one complete suit of clothing and underclothing) disinfected, and then change the clothing they wear for that. The rest of the clothing they bring is sterilized later.

These camps have one advantage over vessels at quarantine—there is always a chance of failing to disinfect all aboard a vessel, especially a vessel in cargo, let the officer take what pains he may. Sailors hide clothing, and while a good officer and trained attendants will seldom fail to find it, yet they may sometimes fail. In sugar cargoes it is not possible—I speak advisedly—for any disinfectant applied to this cargo *in situ* to reach all parts of the outsides of the bags or of the sides of the vessel. The risks can be minimized by sufficient pains, but from such risks the detention camp is free. The applicants are taken one by one and with reasonable care; nothing can enter save with the knowledge of the officer in charge. Also since the camps are used only in times of epidemics, and are close to the infected city, and large numbers come to them only a few hours from the infected city, a considerable number (although a very small proportion) of those who come develop fever.

Cases from Detention Camp Perry, 1888. The hour of entrance into Camp Perry, which marked the time of last exposure, is not given, but the special train from Jacksonville arrived before noon, and at least one suit of clothing was sterilized for each person, and the applicant admitted that afternoon, the remainder of the baggage being disinfected later. We will not be wrong then if we take the afternoon—say to 6 P.M. —as the time of entrance. When the hour of attack is not given, as occurs in some cases, we are in a quandary, as the two ends of a day are twenty-four hours apart; however, as we preface by the words "not less than—days," we must use only the lesser limit, as if the attack had come at the beginning of the day, say before 1 A.M., although about one-half of the attacks do come in the early evening. Allowing thus for imperfect record as well as for the natural difficulties of the problem, our figures for some of these cases then may be about a half or three-quarters of a day too small. They will be marked +.

Camp Perry, 1888.

19. F. L——	" 28	" 31, noon	2 days 18 hrs.

One case included in the reports from Camp Perry I have not used, viz., "C. H——, admitted October 2d, developed yellow fever October 15th at noon." This child, aged eight years, was suspected at the time (I quote Drs. John Guiteras and Geddings) to have been exposed to infection after entrance, and it will be noticed that she was detained with her mother more than the ten days at which pratique was given the remainder, probably from this reason. It is in accordance with my principle to use no doubtful cases in this paper that I do not use this.

The dates of entry are the official record of the camp; the dates of attack and the diagnosis are given by Passed Assistant Surgeon John Guiteras and Dr. Faget. The disinfection was performed by Assistant Surgeon Geddings. The discipline of the camp and general direction were under Surgeon Hutton.

Camp at Dry Tortugas, 1899. This was a maritime quarantine station used as a detention camp, the camp being perfectly isolated from the vessel work. There had been no suspicious vessel even at Tortugas that season, and there was no suspicion of infection of the camp or any part of the station within the walls of the fort.

Passed Assistant Surgeon Smith was in command; Assistant Surgeon Clark, a most careful and painstaking officer, was in charge of the admission and disinfection.

Detention Camp Tortugas, 1899.[1]

7. C. H. B.	Oct. 6, 4:30 P.M.	Oct. 6, night	Few hours.

The camp at Waynesville, 1893, had only two cases of yellow fever develop there: (1) One with an incubation not less than 1 + days. (2) One with an incubation not less than three days.

I regret to be unable to obtain the records of Camp Fontainebleau of 1897 in time for this paper. "Only one case developed over four days after arrival," "the vast majority within twenty-four hours," "there were twenty cases." (Surgeon White's report.) This camp in 1898 yielded no cases of yellow fever. The same is true of Avondale in 1898. Both were small affairs. In 1897 Avondale was a considerable camp, having slightly over one thousand refugees at one time. I cannot get its statistics in time for this article, but my recollection is very clear that there were only two, both on the third day from admission, *i.e.*, incubation not less than two days.

Class II. (C) From the epidemic of Orwood, Miss., in 1897 and miscellaneous sources. Orwood was a country neighborhood, not a town or village; the houses being seldom less than a half mile apart; with a well-disposed, intelligent population, nearly all white. The fever was discovered early, its method of introduction discovered beyond cavil. The conditions were eminently well suited for this class of observation, as well as for that for cases under Class III.

The fever spread primarily from the "Gray House" and the bulk of the cases were contracted at this place. All these save one were observed by Dr. Gant, of the Mississippi board of health, and myself personally, in the beginning of September, and bedside notes made. Much pains was taken to insure accuracy of the dates given, the family at Mr. Gray's and other neighbors

[1] As in Camp Perry table, the shortest time is given.

being questioned as to the dates of the visits as well as the family of the sick. Later on, the record was confirmed by Dr. Mathews in an independent investigation. I believe that every doubtful case has been excluded. The record of No. 7, at Orwood, was made by Dr. Mathews, representing the Mississippi board of health, according to a plan mapped out and agreed on between him and the writer.

1. S. W. G——, exposed to infection at Dr. Gray's in Taylor's, Miss., from July 29 to August 2, 1898, at 6 P.M. He developed yellow fever at the Gray House, Orwood, August 6th, at 11 P.M. Incubation not less than two and a quarter days or more than eight days.

2. P. S——, exposed at Gray House four nights, August 24th to 27th inclusive. He sickened August 29th, 1 P.M. Incubation not more than four and three-quarter days nor less than one and three-quarter days.

3. J. T——, exposed at Gray House several days to August 30th, 7 P.M. First exposure August 25th. He sickened August 31st, 10 A.M. Incubation not less than one-half day, or more than five and one-half days.

4. W. E. S——, exposed at Gray House several times. Last exposure August 30th, 10 P.M. He sickened August 31st, "in the night," *i.e.*, after bedtime. Incubation not less than one day.

5. W. E. S——, Jr., same exposure as above, except that the last exposure was August 30th, at 4 P.M. He sickened September 1st, 2 A.M. Incubation not less than one and one-half days.

6. T. J. R——, exposed at Gray House all night of August 25th and the evening of August 27th. He sickened September 1st, "before day"—near midnight. Incubation a little over four days, or nearly six days, according to which exposure was the infecting one.

7. W. N. W——, exposed at Gray House August 27th, 1 to 6 P.M., again August 29th, 3 to 8:30 P.M. He sickened September 2d, 1:15 A.M. Incubation not less than three and one-quarter, nor more than five and one-quarter days. (Mathews.)

8. Mrs. A——, after being for over a week at Ocean Springs, Miss., where yellow fever was epidemic, returned to her home, a country house near Edwards, Miss., August 8, 1897. She sickened a few hours after reaching home, two days after leaving Ocean Springs.

9. E. A——, a little child of the above, who was with her mother, sickened the next day, two and one-half or three days after leaving Ocean Springs. Period of incubation for Mrs. A. not less than two days. Period of incubation for child not less than two and one-half or three days.

It is reasonable to believe that Mrs. A—— brought clothing from Ocean Springs. Yet, as of ten other people in the house who had not been to Ocean Springs, none developed yellow fever until August 22d, and all had it by August 26th (about the time for the cases developing from the infection from Mrs. A. and child to show), it is simply unreasonable to believe that the fomites in the house should have infected these two. It is fair to assume that they contracted it at Ocean Springs, then badly infected. Still if any one judges that these two are not properly cases under Class II. they may be omitted from the count.

Class III. Here we have not, as in Class II., both dates generally of official record, yet the date of attack usually is; and the date of exposure and the fact of there being no other exposure can in some instances be determined with a high degree of positiveness. I confess, however, that I have not used over one-sixth of the cases reported as of definite incubation, many by good men, on account of some detail not observed or not recorded; or from the information being second-hand; or from merely taking the account from the patient without confirmatory evidence, or collecting the evidence some time after the event, etc. Many of these accounts I believe to be true, but I do not know which ones are not. In the main they agree with the reports which are believed to be without flaw.

1. O. F——, quarantine employee at Chandeleur, considered immune, who had not been exposed to any source of infection that season, went aboard the Spanish bark *Gran Canaria*, July 8, 1890, as ballast master. He left at dinner time, about 1 or 2, changed his clothes, and went aboard a tug, all of whose crew were non-immune, and which did not go about infected vessels. He developed yellow fever, and had a chill on July 11th, in the late evening, 8 or 9 P.M. Incubation a little over three days.

This vessel was from Havana, Cabelleria wharf. None reported sick in port, none was sick *en route* or on arrival; the crew were probably all immune to yellow fever, and consisted of a Manila man and eight Spaniards in the Havana trade for years. The vessel had a rubbish ballast and was dirty; the forecastle was below decks. (Carter, United States quarantine officer.)

2. Schooner *New South*, from Bay St. Louis on June 28, 1891, ran into quarantine limits in a fog and was close to a house in which a case of yellow fever was being treated. About 7 A.M. the vessel was disinfected, that afternoon lay one and one-half miles from the fleet, and a guard was placed aboard. There were only two in the crew. One man developed yellow fever on the evening of June 30th, about 8 P.M. Incubation three days.

This vessel was out for pleasure and the man who was taken sick was immediately from Michigan. The case here given, there being only a single short exposure, fell in Class III., although from a vessel at a maritime quarantine. The date of leaving Bay St. Louis, which was the day before I saw her, was verified. There was a guard on her the whole time from disinfection to the development of the fever. (Carter, Chandeleur Island quarantine station.)

3. G. McM——, exposed at Gray House, Orwood, an infected locality, August 23d, 2 to 6 P.M. He sickened at 12 noon, August 29th. Incubation five and three-quarter days.

4. Mrs. J. T——, exposed at the same place less than an hour, once only, August 29th, 4 P.M. She sickened Septembed 1st, 4 P.M. Incubation three days exactly, a clear definite case, very carefully observed and investigated. This was the wife of J. T——, No. 3 of "C, Class II."

There were eight children in this house, three of whom, the youngest, slept in the room with Mr. and Mrs. T——. None of the children developed fever until twenty-nine days after the sickness of Mrs. T——, when the house had time to become infected from Mr. and Mrs. T——; then all who were about the house developed it within a few days. It is not reasonable, then, that Mrs. T—— should have contracted the fever from the clothes worn by Mr. T—— from the Gray House, else some of the children would have taken it earlier from the same source. He wore his working-clothes, and they were hanging up in the room when I was in the house, the children being in the same room.

5. A. J——, exposed at Gray House, the night of August 27th to 7 A.M. August 28th. He sickened August 31st at 8 P.M., but aching began about noon. Incubation not less than three and one-half days or greater than four days.

6. P. R——, at Gray House August 25th, 5 P.M. to 8 A.M. August 26th. He sickened August 29th, 9 to 10 A.M. Incubation three days.

7. L. O——, at Gray House August 13th and the evening of August 18th. He sickened August 22d, 3 P.M. Incubation four days or nine days. The former is more probable, as we have no record of any one who had

been exposed at this house developing fever as early as the 13th.

8. Mrs. R. J. C——, at Gray House, 10 A.M. to 4 P.M. August 29th. She sickened September 2d, 11 A.M. Incubation three and three-quarter days.

9. L. M. W—— went from Clinton to Col. Champion's funeral at Edwards, Miss., September 7, 1897, arrived about 11:30 A.M., and left that afternoon. He developed yellow fever at Clinton, September 10th at night. Incubation a little over three days.

10. M. C—— went to Col. Champion's funeral at Edwards, Miss., September 7, 1897; left for Nita Yuma, Miss., the same evening. He carried nothing but the clothes he wore. He developed yellow fever, the first case at Nita Yuma, September 11th at night. Incubation four days.

11. R. F——, exposed at Taylor's, 8 P.M. August 29th to 5 P.M. August 30th. He sickened September 3d, 2 A.M. at home, about nine miles distant. Incubation three and one-half days. (Dr. Mathews.)

12. Mrs. J——, exposed to infection at hotel in Taylor's, Miss., from noon of August 27th to 6:30 P.M., when she left for home, a country house near Waterford, Miss., thirty or thirty-five miles distant. She sickened September 1st, in the morning before day. Incubation four and one-half days. (Haralson and Carter.)

The following four cases, one family at Taylor's, were reported by Dr. Haralson. They were copied from his note-book by the writer on the morning of September 9th, within fifteen minutes of his leaving Mr. L——'s house. The visits herein recorded as made to the hotel of Mr. Williams were investigated by the writer and found to have been made at the dates and hours specified.

Misses L. and E. (aged five years) and G. (aged one year) went in the morning of Wednesday, August 3d, about seven o'clock to Mr. Williams', a badly infected place. Mrs. L——, Mr. L——, and Gladys went in the afternoon of the same day to the hotel at Taylor's, also a badly infected place. After going home, about one-fifth of a mile distant, they heard that the fever was announced as yellow fever, and the children and Mrs. L—— remained strictly within their own premises and Mr. L—— kept away from the other houses. Earl developed yellow fever early in the morning (5 A.M.) of September 8th, the other three during the night following: Mr. L—— about 8 P.M., Mrs. L—— about 11 P.M., and Gladys about midnight.

13. Incubation: Earl, eight days or little less.

14. Incubation: Mrs. L——, eight days, or eight and one-quarter days.

15. Incubation: Mr. L——, eight days.

16. Incubation: Gladys, eight and one-quarter days.

Frank (aged six years), the only other member of the family, and who was not with the others on August 31st, did not develop fever until in October.

With reference to the above the writer has disregarded a principle which he had followed strictly in other cases in this paper, *i.e.*, he has accepted a case as of only one exposure when there were several foci of infection accessible to the person developing yellow fever. There were unquestionably several foci of infection at Taylor's, besides the two visited by the L's on the 31st, some of them not then recognized. Yet as there were none on their side of the railroad save Williams', and as they tried to isolate themselves from all neighbors, and especially as we have a very clear history of an exposure of four people and all of the four developed fever practically at once, while the fifth not exposed with them did not develop it until the house had had time to become infected, it seems fair to accept it as genuine in spite of the above principle. The case, too, is strengthened by the fact that two of the patients were babies and could have gone to a neighbor only with their parents. They kept no servant.

16	cases					

Here twelve cases in which, it is believed, that we can claim without cavil that there was only a single exposure, give periods of incubation of from three to six days. The four which give eight days' incubation are believed also to be reliable, but the matter has already been set before the reader, who can judge for himself. In the opinion of the writer, this table is more valuable than either of the others. It is worthy of note that of twenty-eight cases which give us a chance to determine the minimum period of incubation, none gives it below three days, three giving that figure, and ten not more than 3+.

This ends my article. The writer has been engaged in collecting these observations since 1887, and it was his intention to combine with them all such as he could find reported by others to be reliable, before giving them to the public. To have waited to do so, however, would have missed this opportunity of presenting them to an audience, of all others the most interested and the most competent to judge of this subject and thus most capable of correcting such errors as he has fallen into. For the same reason, lack of time, the records of Camp Fontainebleau were not used. The complete work yet remains to be done. Save the five cases which Wilkinson published, none of these cases has been previously used for this purpose. Yet they are believed to be by much the most complete data to this date on this subject, the impor-

tance of which to maritime quarantine we all recognize.

Of the cases from these notes the shortest incubation recorded is three days, the longest eight and one-quarter days, while very few of the cases show over six days. It is not claimed that cases of longer or shorter incubation than any one recorded here may not occur; or, in spite of the pains taken, that there are no errors in any of the cases I have given, yet it is believed that there is none which will vitiate any general conclusion which can be drawn from this paper.

To conclude, while it may be that this question can be determined more readily, certainly with far less time and labor, simply by observing the time between the inoculation of the disease by an infected host and the development of the fever in the subject; yet, even if so, it is well to compare the findings of observations on nature's experiments with those from direct experimental research, although the first lack the precision of the latter when we choose and control all the conditions of the problem, and the making of them is certainly less satisfactory.

A CONTRIBUTION TO THE BOTTINI OPERATION FOR THE RADICAL RELIEF OF PROSTATIC OBSTRUCTION.[1]

By L. BOLTON BANGS, M.D.,

NEW YORK,

PROFESSOR OF GENITO-URINARY SURGERY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL SCHOOL; SURGEON TO BELLEVUE HOSPITAL, ETC.

The treatment of prostatic obstruction continues to be of unflagging interest. Inasmuch as about one-third of all men have, after the age of forty-five or fifty, evidences of this affection, the question of what we shall do for them becomes correspondingly great. It seems to be such an inevitable malady that measures of relief may have attached to them a personal interest which no other circumstances can arouse. The observation of distress in other men may stir our sympathies and provoke our professional enthusiasm for their relief, but when we reflect that possibly we ourselves, young and old alike, may be sufferers also, the objective lesson will become real and vigorous.

Many a man who has worked hard all his youth and laid the foundation for success in mid-life, finds himself brought face to face with a series of symptoms which gradually undermine his vital force by loss of sleep and by repeated attacks of prostatitis and cystitis. Furthermore, when he ought to be free to do his best work unhampered and untrammelled by any consideration of bodily discomfort, he finds himself subjected to the tyranny of that palliative means, which we call "catheter life." Of course, many a man compelled to this means of palliation goes on comfortably for a time, but he is always liable to infection of his bladder and kidneys, and on the whole, even at the best, it is a life of continuous slavery.

In my opinion, enlargement of the prostate is not a senile condition at all; its effects may not show themselves till mid-life or later, but it really begins in early life. It is a common experience that the premonitory symptoms of this malady begin shortly before or at fifty years of age, but they are made light of by the patient, and no attention is paid to the cause of them till other and more serious secondary conditions have begun to manifest themselves. Hence it would be well if we could impress upon the community the wisdom of attending to these early symptoms; for, even if palliative measures only are employed at first, it may be that radical means will be demanded later, and, therefore, the earlier we know this the better. In general it may be affirmed that the younger the subject the less the risk of these radical measures; but, anyhow, if radical relief can be had, all questions relating to it become highly important and merit our most careful consideration.

Any surgical attack upon the prostate gland is a serious matter. It is especially so when undertaken after the pathological changes due to hypertrophy have ensued. Hence it should not be undertaken lightly, but with careful consideration of the factors in each individual case. Observation of results, not only of my personal work but of the work of others, convinces me that this statement is not too emphatic. Indeed, the operation which thus far has promised the most for the patient and which seems the most satisfactory to the surgeon, namely, prostatectomy, is, even in the hands of the most skilful, followed by a grave mortality. The more radical the operation, the greater the risk. That this is so is strongly substantiated by a moment's consideration of the function of the gland, of its relation to important nerve centres, and also of its abundant lymphatic endowment which, together with the free anastomosis of its veins with the great portal circulation, renders the gland a peculiarly dangerous focus of infection. In view of the anatomy of the organ and of accumulated clinical facts, I have been extremely conservative in my treatment of prostatic cases, and have reserved operative measures for such as imperatively required it. Hence, when the galvano-cautery operation, devised by Bottini and practised by himself since 1875, came to my knowledge, it did not appeal to me as a scientific surgical measure. I followed the teachings of the "English school," and gave no attention to it, but since its revival and improvement by Freudenberg, of Berlin, I have watched and tested it with great interest; for if we can radically cure, or even improve, the conditions from which so large a proportion of men suffer, without serious risk and with a minimum of detention, we should welcome such a means, and test its claims without prejudice.

After an experience of nearly three years with the improved Bottini operation, I feel warranted in stating that we have such a means; but, in making this statement, I wish to state also that my experience does not contradict or invalidate the proposition which I have just made. Notwithstanding the statements which have from time to time appeared in the journals regarding this operation, it is to be regarded as a serious matter. Persons to be subjected to it should be as carefully prepared as for any other important operation, and the state of their vital organs more carefully considered than for operation upon a region not in relation to the urinary apparatus. Nor is the operation itself so simple as it would appear: it is an operation of skill. Its technique is not multiform, but each detail requires care and unrelaxed attention of the operator on each occasion. Furthermore, the number, locality, and length of the incisions are determined largely by the tactile skill of the operator. Preliminary measurements must be made. Preliminary cystoscopy is a material help, but in some cases cystoscopy is an unnecessary instrumental irritation, and in others impossible or unwarranted.

The choice of the anæsthetic is important. To determine this a careful study must be made of the subject; a phlegmatic, insensitive individual, in whom the incisions to be made are short ones, may easily have it done with local anæsthesia; but as in my opinion the operation is best when very slowly done, the majority of cases should have a general anæsthetic. The

[1] Read at a meeting of the New York County Medical Association, February 18, 1901.

Since the above paper was read I have had two more operations, making thirty six in all. One of these patients died from sepsis on the fifth day after the operation, making two deaths directly due to the operation.

slowness with which the operation is done is the best guarantee against the serious secondary hemorrhage which operators have reported from time to time. The majority of patients operated upon under local anæsthesia suffer more or less pain during the operation.

There are certain symptoms following the operation. Some of these may be regarded as almost constant, and others as occasional, but which may occur. The first of the more constant is frequent urination. This is variable. In some individuals immediately after the operation, and for twenty-four or forty-eight hours thereafter, the demands to urinate may be every half-hour or hour, gradually diminishing in frequency. There is usually scalding during each act of urination, but this is also variable in degree of severity and gradually diminishes, rarely lasting over three or four days. Some blood mixed with the urine may be expected immediately after the operation. It rarely lasts over forty-eight hours, and but one of our cases had a small amount for four days. If the operation has been slowly done, the admixture of blood is very small. One-third of our cases passed bloody urine, and the rest had no blood. In from one to three weeks after operation a certain amount of secondary hemorrhage may be expected, at the time when the destroyed tissue makes its appearance. It is apt to occur at the end of the act of urination, and be enough to tinge the urine. In one of my patients, on two occasions, there were some drops of free blood. Pain after the operation may be expected. This is of a burning character, and is relative; the degree of suffering varying with the susceptibility of the individual. Ten of my thirty-four cases required morphine hypodermically for the relief of this pain. It rarely lasts over a few hours. At the end of the first week, but usually from the tenth to the fourteenth day, burned tissues may be expected to appear in the urine. They are generally in minute particles, black or brown, having a distinct burned odor.

In my experience a rise of temperature after the operation occurred with sufficient frequency to warrant me in classing fever among the symptoms to be expected. Ten of my thirty-four cases had fever. Six of these had distinct chills, coming on about twelve hours after the operation, and three of these had a temperature of 103° F. In all cases the fever subsided at the end of the third day. As to the symptoms which may be called occasional, but which may occur: First, is a slight grade of shock. This happened to one of my patients—a weak old man of seventy-one. Secondly, macroscopic masses of tissue will occasionally slough off (sometimes causing obstruction to urination), and be ejected from the urethra with difficulty and only after straining efforts. In one case, in order to quiet the patient's bladder, I was obliged to pump out some of these masses in the same way that fragments of stones are evacuated after a litholapaxy. Thirdly, epididymitis may occur. This took place in two cases.

In my opinion, the post-operative period is more nearly three weeks than two. Many patients may with safety be allowed to sit up at the end of a week, but they should not be allowed to resume their ordinary mode of life for at least two weeks, and many not for another week. Moreover, and this I wish to emphasize, the after-treatment of all these cases is almost as important as the operation itself. A large granulating surface is to be healed, and in most cases an old cystitis is to be treated. These demand careful local attention for an indefinite time, and the patient should not be allowed to pass from observation till the urine is clear, and the urethra free from all sense of burning and irritation. If possible, the patient should finally be explored with the cystoscope.

Are there accidents or complications following the operation as a result of it?

Yes, there are. Incontinence of urine has followed two of my operations. These patients are still under observation and are slowly improving, but the annoying involuntary escape of urine persists, especially while they are standing or walking. In one of these individuals there has been apparently an occlusion of the seminal ducts.

The cases upon which this paper is based are commonplace as regards their symptoms and diagnosis. Therefore it is unnecessary to weary you with a recital of them, but my first case was so instructive in its relation to the technique of the operation that you will permit me to present its principal features as a matter of interest.

This patient was aged seventy at the time of the operation. He has suffered extremely from repeated formation in the bladder of phosphatic calculi, which have been removed by various forms of operation. At this time, although he can pass a small quantity of urine spontaneously, he is entirely dependent upon the catheter, its use being necessary at intervals of from one to three hours. There is a marked grade of vesical catarrh, which persists in spite of systematic irrigations. He has also a number of calculi in the bladder. The possibility of performing upon him the radical operation of prostatectomy had been repeatedly considered; but in view of his poor general condition and of a marked chronic nephritis, this was rejected and the advisability of the Bottini operation was decided upon.

In view of the presence of stone and the severe cystitis, it seemed best to open the bladder above the pubes, remove the stones, at the same time do the Bottini operation, and then give the bladder the benefit of rest by prolonged drainage. This accordingly was done in May, 1898. After the removal of the stones, the wound was held widely open by retractors, and the Bottini-Freudenberg instrument introduced through the urethra. The prostate was unequally enlarged to about the size of a small lemon, projecting into the cavity of the bladder. Two grooves were cut into the prostate with the blade of the instrument, one inferiorly and the other horizontally. The inferior one was three centimetres in length. Before the horizontal incision was completed, the battery gave out. I said to myself, "If it is only a question of cauterization, why not use the Paquelin cautery?" and accordingly the operation was completed with the latter instrument. Here come the instructive features of the operation:

It was observed that when the blade of the electric instrument, heated to a white heat, was brought in contact with the tissues, it immediately became of a dull red; and when the action of the battery fluctuated, it became of a still duller hue. There was also a remarkable difference between the action of the galvano-cautery and that of the Paquelin cautery—a difference not easy to describe, but unmistakable when seen. The action of the galvanic instrument was, so to speak, subtle or refined, leaving a very fine, delicate eschar; but another effect, which I cannot put into language, extended into the contiguous tissue beyond the eschar formed by immediate contact with the knife. On the other hand, the Paquelin instrument seared grooves in the structure of the prostate, but it left a thick, leathery eschar, and there was none of that secondary effect which accompanied the action of the galvanic instrument.

Continuous bladder drainage was established through the suprapubic wound. The patient had no hemorrhage at any time, but required suppositories of opium for the relief of pain. From that time till the present he has remained so comfortable, as compared with his

previous existence, that he has absolutely refused to have the suprapubic tube removed, contentedly bearing with its discomfort. I am unable to say whether anything has been gained for him by the Bottini operation, and his case is included among my percentage of failures. I narrate his case thus in detail only to illustrate what it taught me in the way of technique:

1. That the flow of electricity must be maintained to a degree which will keep the blade at white heat.

2. That in measuring a given case for the length of the incisions, allowance must be made for the action of the galvanic cautery beyond the distance at which the knife shall actually penetrate.

3. That the operation must be done with great slowness, in order to prevent hemorrhage and to get the best results.

Now, what results have been obtained?

I have had thirty-four operations; three patients have been operated upon twice; one had only what is termed a "bar" at the vesical neck; the others were all cases of prostatic enlargement. One patient had had a previous prostatectomy. Another patient, two years before the Bottini, had been subjected to castration; but when he came to me he still had six ounces of residual urine, and, in addition, calculi in the bladder. After the Bottini operation, which was done in May, 1900, he had two ounces of residual urine, which is still diminishing in quantity, and he is now able to void all but one ounce of a measured quantity of fluid injected into his bladder. He is classed among those who have been improved only.

The ages of my patients varied from forty to seventy-five years, and the longest catheter life was fifteen years. About fifty per cent. were wholly dependent upon the catheter; about twenty-five per cent. could urinate a little spontaneously, but were obliged to use the catheter chiefly. Six patients had not begun the use of the catheter regularly or systematically; they had residual urine varying from two ounces to eight ounces, but all had more or less catarrh of the bladder requiring the use of the catheter on the part of the physician, for purposes of treatment. Sixty per cent. of those operated upon have discontinued the use of the catheter, either having no residual urine or but an inconsiderable amount, varying from a few drops to a drachm or two. Twenty per cent. have an increased amount of spontaneous urination, and are able to reduce the use of the catheter from one-half to only that which is required for occasional treatment. Twenty per cent. received no benefit; or, if any, but very little. The largest percentage of cures was among the patients wholly dependent upon the catheter; that is to say, eighty per cent. of the fifty—forty per cent. of the whole number of cases. Of the three patients upon whom the operation was repeated, but one received benefit. He had had almost maximum relief from the first operation, and requested the second operation because he was subject to attacks of prostatic congestion, during which his residual urine increased. Since the second operation he has discarded his catheter altogether, and has residual urine of half a drachm or a drachm, the variation in quantity apparently dependent upon the attention which he bestows upon the act of urination. The other two were not benefited by either operation.

The time for voluntary urination to appear after the operation has varied, the shortest period being immediately following the operation, and the longest two months thereafter; the latter apparently depending upon the contraction of the cicatrices. I have had one death directly attributable to the operation; the patient died of acute sepsis twenty-four hours after the operation, the posterior incision having probably opened the deep urethra. There were two other deaths which occurred about three weeks after the operation; whether they had any relation to the operation or were hastened by it, I cannot say; I will narrate them to you and leave you to judge, but as they took place within what I call the "post-operative period," I think they ought to be reported.

The first was that of a patient who, five days after the operation, developed "cardiac attacks" to which, it was ascertained, he had been subject for years. As he told me, he often had to lie down on the ground, sometimes on the snow, till the attack passed away. He had a rapid pulse, stertorous breathing, livid lips, cold extremities, and was partially unconscious. On the twenty-fifth day after the operation he died in one of these attacks.

The second was a death from uræmia, following an alcoholic debauch. The patient left the sanatorium ten days after the operation and went upon a spree; his old nephritis lighted up, and death ensued on the twenty-second day after the operation.

Now, then, as to the permanency of results, of course, time only will tell. While I do not believe that the destroyed tissue can ever be regenerated, it may be possible that, the causes of prostatic enlargement still operating, some of these patients may have a return of their symptoms. But it seems to me that the subject is so important, possibly to some in this audience, that if any patients who have been operated upon by this method should come under our notice, we ought to go into their former and recent histories carefully, examine them without prejudice, and, if possible, communicate with the operator, in order that we may not only determine the cause of failure, if any, but also candidly and frankly ascertain the merits or demerits of the operation.

In regard to my twenty per cent. of failures, I am unable to explain them; the same care was applied to them as to the patients who were cured. I offer the explanation that possibly that portion of the prostate which we call "extravesical," to the action of which I called the attention of the profession some years ago, and which cannot be reached by the galvanocautery knife, may be the cause of failure in these cases.

In all these operations I have been assisted by my associates Drs. Pedersen and Squier, and to them I am indebted for aid in the preparation of this statement of my experience.

ACUTE GASTRIC ULCERATION.

By Prof. H. NEWTON HEINEMAN, M.D.,

NEW YORK.

In 1889 I made an autopsy at the Mount Sinai Hospital, New York, upon a woman twenty-two years of age, who had died after twenty-four hours' illness of sudden and large hemorrhages, the nature of which was doubtful, but which were supposed to be hæmoptyses. At the autopsy some blood was found in the lungs, and the stomach contained over a litre. Although my notes say that a superficial erosion, nearly two centimetres in diameter, was found near the cardiac end of the stomach involving the mucous membrane only, it was attributed to post-mortem change, and for want of a better diagnosis, bronchial congestion with resultant hemorrhage was entered upon the record with a question mark.

Recently, while spending my winter in Paris, a series of accidents brought me: first, an opportunity of studying the pathological conditions in a case of gastric ulceration; and secondly, contact with Dr. Cazin, who had in the absence of his superior, Professor Duplay, of the Hôtel Dieu, been called on to operate upon

the case of Professor Dieulafoy, which operation had proven a success. Dr. Cazin, who besides being surgeon is likewise a pathologist of high rank, repeatedly discussed the pathological condition of this and similar cases with me, and the opportunity of carefully studying all his private notes of this case, together with the specimen mentioned above, at the laboratory of Dr. Latteux, has interested me sufficiently to induce me to publish the results of my review of the subject.

Then, too, the discussion upon the subject recently held in New York and reported in the MEDICAL RECORD of December 8, 1900, seems to have called forth from Dr. Einhorn the remark that Dieulafoy's cases were of an infectious nature. Dr. Einhorn is, in my opinion, both right and wrong. He is correct in adhering to the quotation from Dieulafoy, who believes for the most part that a toxic infection was probably at the bottom of his cases. He is incorrect according to my views—and I also believe that even Professor Dieulafoy should not be quoted too literally in his conclusions in this instance—for I cannot help thinking, first, that Dieulafoy has by an inadvertence been led to incorporate certain clearly infectious cases with his own cases and those of others of a non-infectious character. That this is probably so I am led to believe, since Dieulafoy has in certain of his clinical records[1] alluded to these ulcerations as possibly being "early stages of the chronic ulcer."

The cases of "acute gastric ulceration," for such Dieulafoy suggests calling them, as distinguished from the well-known "gastric ulcer," have up to within a few years been overlooked, but because of their importance deserve consideration.

Whether Dieulafoy be correct or not in his etiology, his masterly description of the condition and his records of his own cases and those of others deserve rehearsal, since we must give him credit for having first "clearly" set forth the condition.

Professor Dieulafoy's first case is briefly as follows: On the eve of November 13, 1896, a man, twenty-seven years old, was carried into his ward in Hôtel Dieu. He was deathly pale and appeared exsanguinated, as one who had suffered from serious hemorrhages. In a feeble voice he stated that since the preceding morning, started by an effort at lifting, he had vomited a total quantity of two or three litres of blood. Although the condition of the young man pointed to a profound loss of blood, the reported quantity was considered exaggerated. After careful questioning the diagnosis of a commencing ulcer of the stomach was made. Besides rest, the usual medication was resorted to, acidulated cold drinks were given, and ergotin was injected. Despite this, during the night he raised (by measure) two litres of fluid and clotted blood, which was followed, as was his first attack, by jaundice. As the patient estimated the quantity as being the same as on the preceding occasion, it represented a loss of four litres of blood in less than twenty-four hours. Recognizing the gravity of the case, intravenous injections of artificial serum were made. His condition improved, but in the early afternoon another hemorrhage of one litre followed and the patient died.

The autopsy presented the following result: The outer aspect of the stomach was normal except for an ecchymotic spot, about 2 cm. from the cardiac end, nearer the greater curvature, and a few slight adhesions of the omentum near the gastro-hepatic and gastro-splenic folds. Both ends of the stomach having been ligated it was taken out, cleared of one and a half litres of blood, and despite careful search nothing was found. The mucous membrane was now subjected to a careful washing, when a very superficial ulcer was discovered 2 cm. from the cardiac end, circular in shape and involving nearly the area of a silver dollar[1] (five-franc piece). The stomach was normal throughout except at the seat of the ulcer, which was without indurated base, of a grayish-white color, and presented two or three small ecchymotic spots and crater-like erosions. One of these erosions showed a small arteriole with gaping mouth, into which a pin could be introduced. Microscopic examination demonstrated that the mucus coat and muscularis mucosæ alone were involved, the latter only in places. It was in one of these erosions (owing to the disappearance of the muscularis mucosæ) that the gaping arteriole was located. This arteriole and the arteries in the vicinity were absolutely free from endarteritis or periarteritis and every possible degeneration, so that obliterating endarteritis could be excluded. The neighboring veins were dilated and thrombosed, and explained the ecchymotic spots referred to. All that could be discovered was a superficial ulceration which had directly eroded and eaten its way into the arteriole, from which the patient bled to death.

It was this case and the autopsy findings which induced Professor Dieulafoy to decide upon operative measures at the next opportunity, and not to rely upon medication and serum injections alone. The opportunity came on October 13, 1897, when a man, twenty-two years old, entered his service in the Hôtel Dieu with the following history: Six days previously, after a hearty evening meal, he was seized with nausea, and vomited, as he thought, one or two litres of pure, bright blood. He went to bed and slept well. The succeeding night, having eaten well during the day, he again vomited a considerable quantity of blood, partly fluid and in clots. Since then he had not raised any blood, but was so weak that he sought hospital aid on the evening of October 13th. His appearance on the following morning was very striking and his pallor extreme, involving the skin and all mucous membranes; the pulse was small, temperature 38° C. (100⅘° F.), and the patient extremely weak. The statement that three or four litres of blood had been lost was borne out by the serious red blood globule diminution (1,600,000 to the cubic millimetre). Careful investigation of the history and of the lungs and the absence of all cough excluded hæmoptysis, and cirrhosis and its consequent pathological conditions were also excluded, limiting the diagnosis to ulcer or cancer of the stomach. The latter was finally excluded, and the diagnosis was limited to simple ulcer, although the patient up to the time of the hemorrhage had never had any gastric symptoms. Professor Dieulafoy then recorded his impressions, which were that he felt he would not again be justified in seeing a patient bleed to death without an operation. But, inasmuch as no bleeding had taken place in seven days, he decided upon medical treatment, with the reservation that, inasmuch as the red blood globules were reduced to less than one-third the normal, he would insist upon surgical interference at the first renewal of severe hemorrhage. All went fairly well till the night of October 15th to 16th, when the hemorrhages suddenly supervened, and in the morning a basin containing a litre (by measurement) of fluid and clotted blood was shown Professor Dieulafoy. The patient had a cadaveric hue and was completely exhausted, almost dead. Feeling there was no time to be lost, and in the absence of the superior surgeon Professor Duplay, his chief assistant Dr. Cazin was asked to operate without delay. Dr. Cazin was so little sanguine that he asked Professor Dieulafoy to try and build up the patient first before operating. Professor Dieulafoy felt that the patient's only chance for his life was immediate surgical intervention, for he had come to the end of medical resources, and was certain that serum injections alone could never stop the hemorrhage.

[1] Clinic of Professor Dieulafoy, Hôtel Dieu, 1897–98.

[1] Both pieces have about the same size.

Dr. Cazin's notes, placed at my disposal, describe the operation as follows: Preparations for a laparotomy and for coincident intravenous serum injections were made at once. The patient having been chloroformed, an abdominal incision 12 cm. long was made parallel with the left border of the free edges of the false ribs (left side), following Labbé's line. The stomach was drawn out, and despite careful examination not an adhesion, nor induration, nor any mark of any kind was found anywhere on the surface. The stomach, which contained some liquid, was carefully emptied by manual compression, the contents being gently forced into the intestine; a clamp, guarded with rubber, was placed close to the pylorus to prevent regurgitation into the stomach. The stomach was kept outside the body, covered with warm compresses, and an incision of 6 or 7 cm. was made, following the line of curvature and nearer the lesser than the greater curvature, so as to avoid the larger gastro-epiploic arteries. For want of room to explore the stomach, the incision was increased up to 10 or 11 cm. A few hæmostatic clamps were applied to both lips of the wound, and the stomach was carefully sponged out with long-handled sponges. Now, despite careful examination, nothing was at first found when the stomach was carefully turned inside out over the hand, like a glove. Not until the mucous membrane was everywhere carefully dried with sterilized gauze, which demonstrated the pyloric portion to be absolutely healthy, was the lesion found in the cardiac portion. On the posterior wall of the cardiac end, near the greater curvature and near its upper extremity, an ecchymotic spot, somewhat elongated and of the size of a pea, was found, in the centre of which was a small ulcer from which a little blood exuded. This formed the approximate centre of a superficial ulcer, 1 cm. in diameter, which contained three other recognizable bleeding points, each in the centre of a more marked erosion, each of which had a diameter of 1½ to 2 mm. The entire ulcer was enclosed by a circularly arranged catgut ligature and suture, involving and transfixing the mucous membrane all about the ulcer. Three layers of suture closed the wound: the deepest muco-muscular layer being a continuous catgut suture; the other two layers, the sero-muscular and serous layers, separate silk sutures. The abdominal wound was closed with silver wire.

During the operation 1,500 gm. of serum were injected into the veins of the arm, 500 gm. subcutaneously during the succeeding night, and upon each of two succeeding days 500 gm. Champagne and water were allowed on the day following the operation and continued, and two peptonized enemata were given, with three on the second day after the operation. The patient rapidly improved, and on the ninth day after the operation the sutures were removed, the abdominal wound being firmly united. Following this semi-solid food was allowed, and after the twentieth day meats were given. The patient's appetite was voracious; he rapidly recovered strength, and at the end of five weeks was discharged cured. He reported some months later and again recently (autumn, 1900), and was in perfect health.

Professor Dieulafoy adds a case, personally reported by Professor Michaux, in a washerwoman twenty-three years old. She had always been well, with the exception of stomach cramps lasting a few days, up to October 20, 1897. On this day, though having stomach pain, she went to work, was seized with vertigo, and soon vomited a large quantity of blood (estimated at two litres). This was followed by jaundice. She was treated medically at home, but on the 23d new hemorrhages and renewed jaundice followed, and on the 25th she entered Professor Michaux's service. Her mucous membranes were absolutely without color; pulse, 130; temperature, 39° C. (102° F.). Medical treatment failed entirely. Operative procedure was decided upon and carried out, and nothing was found; nor were there any adhesions or spots of induration. It is fair to state that the operation was hurried and had to be prematurely completed on account of the desperate condition of the patient. The fever continued and was followed by delirium and nervous symptoms and renewed jaundice, evidence that internal hemorrhage continued, though no blood was vomited, and on the 31st of October the patient died.

The stomach, which was placed at the disposal of Professor Dieulafoy, was examined by him, and was described as follows: In the posterior wall of the mucous membrane, nearer the lesser curvature, a superficial simple ulcer was recognized only when the stomach folds were obliterated or flattened out. This was about 2½ cm. in its entirety, and by the aid of a pocket lens one could see a central erosion with an open gaping arteriole, surrounded by slight ecchymotic spots.

Microscopic examination demonstrated the ulcer to have been formed at the expense of the mucous and muscularis mucosæ layers, all other layers of the stomach wall being healthy; nor was the artery involved at all degenerated, except for the eroded point. These cases were all thoroughly investigated, and in the case operated on and in those in which autopsy was made no evidence of anything was anywhere found either in the stomach or in the body, beyond the ulceration and its eroded arteriole. That this was sufficient to give rise to such severe hemorrhage is carefully dwelt upon by Dieulafoy, who calls attention to the fact that the gastric arterioles involved are quite as large as the small arteries of the fingers, whose readiness to bleed freely we well know.

In this same category belong the following cases, referred to by Dieulafoy himself, which were communicated to him personally: one by Gilbert, in a woman, who died, and at the autopsy the assistant reported he could find nothing. Upon searching carefully Gilbert himself found a simple ulceration, 1¾ cm. in diameter, with an eroded arteriole.

Gilbert reports a previous case of a woman of thirty years, who was operated on and nothing was found at the operation, to which she succumbed after a few days. At the autopsy only a minute search revealed the source of hemorrhage, which proved to be a small, simple ulceration with an eroded arteriole.

The case of Luys' is next referred to. A man, thirty-five years old, who was indisposed, complaining only of gastric pains of a few weeks' duration. He admitted having drunk excessively for some months, and died suddenly on the day succeeding his admission to the hospital, in an attack of syncope preceded by sudden pallor. The autopsy revealed a simple ulceration, involving only the mucous and muscularis mucosæ layers, and the stomach was filled with over two litres of fluid and clotted blood. The walls of the stomach were normal in other respects, and there could be no question but that the ulceration was of recent date.

In reference to the following cases, which Dieulafoy quotes under the same category, I must say that I do not regard them as of the same nature beyond the fact that gastric ulceration was found.

Thus the case of Lepine and Bret, referred to, is that of a man sixty-five years old, with extensive endarteritis which involved all the gastric arteries as well, and in whose stomach several of the degenerated arteries were the seat of ulceration.

Much less should the following cases, whose nature is infectious beyond any question, have been included under the category of cases of simple acute gastric ulceration.

Thus in the case of Brault, referred to by Dieulafoy and communicated to him, extensive glandular ulcera-

[1] Luys: Bullet. de la Soc. Anatomique, 1896, p. 660.

tion, infiltration of the mucous membrane by young lymph cells about the ulcer and at some distance from the ulcer, was also met with, the case evidently being one of infection.

Similarly a case by Girardeau,[1] referred to, must be regarded as belonging to the decidedly infectious, for the bleeding vessel was surrounded by miliary abscesses containing numerous micro-organisms.

Pathology.—Attention has already been called to the fact that even when an arteriole only is involved, we are dealing with an artery whose hemorrhage may become serious. The great source of danger arises from the fact that the arteriole is eroded only to a small extent of its circumference, thus keeping it patulous and preventing retraction within the sheath of the vessel or formation of clot which would arrest hemorrhage. The arteries involved were, in twenty-three cases collected by Savariaud,[2] the splenic in seventeen cases and the coronary gastric arteries in six cases.

Having been favored with the opportunity of reviewing the gross and microscopic lesions in two of the cases referred to, I failed to find any lesion of the gastric mucous membrane beyond those already mentioned; and a careful review of the bacteriological work left nothing to be criticised, so that the lesion can be described only as an acute ulceration of the mucous membrane, or of this and the muscularis mucosæ, unaccompanied by any bacterial invasion and without other recognizable lesion in the walls of the stomach. A suggestion which will prove of service in microscopic examination is the employment of carbolated xylol instead of oil of cloves. The former preserves the tissue about the edges of the ulcer, and by causing less translucency permits of the recognition of any young cells which may be present. The seat of the ulceration involves an area ranging in size from a pea to nearly three-fourths of an inch. When small it is easily overlooked; and all the more so because it is without indurated edges. The situation of this ulcer may be anywhere, though it is most often found near the cardiac end, in the grand cul-de-sac, or the anterior wall near the greater curvature. The chronic ulcer affects these parts less.

Etiology.—The causes have been ascribed to gastric hyperacidity. Again it has been maintained that we are dealing only with an acute stage of the chronic ulcer. Chronic alcoholism has been given as the cause, and finally some toxic or infectious influence.

In reference to the question of hyperacidity, in only one case of Dieulafoy was an examination made and decrease of acidity found; in one other case a moderate hyperacidity was noted, but it is far from satisfactory to accept this as the cause of the trouble, at least for the present. It is true that most men in whom the ulcer was met with were hard drinkers, but no proof exists that alcohol in the form of even the strongest beverages can produce such a condition.

In reference to toxic or infectious causes Dieulafoy mentions the following facts: that Letulle produced gastric ulcers in guinea-pigs by overdistending the stomach with bicarbonate of sodium and then injecting staphylococci into the peritoneal cavity; and that Guiquez and Hallion[3] did the same thing by injecting diphtheritic toxin beneath the skin of the belly in the guinea-pig.

While admitting and accepting the above, such experiments confirm only the cases in which infection was recognized to be present, but which I do not include in this group; they have no bearing on the class of cases found to be entirely free from infection of every kind. Still Dieulafoy presents this as a possible cause.

Savariaud believes the ulcer to be an early stage of the chronic ulcer; and this would seem to be the most plausible theory were it not for the fact that the ulcer may be found where the chronic ulcer usually is not present. Dieulafoy says that time must elapse before the proof is established that such an ulcer can precede or be transformed into a chronic ulcer.

Clinical History.—Usually the sudden and excessive hemorrhage is the first sign, and sometimes the only sign or symptom of the trouble. Exceptionally nausea and gastric pain, vertigo, and syncope immediately precede and accompany the hemorrhage, the patient being previously in usual good health. Exceptionally there are prodromata, such as nausea and vomiting, accompanied by gastric pain; and if the blood is retained, sudden pallor may alone lead us to suspect the trouble, beside thready pulse and even chills and convulsions. The loss of blood may give rise to a slight elevation of temperature, a condition sometimes found in chlorotic women.

It is in infectious cases, not those here considered, that we have a noticeable rise of temperature, 102° to 103° F. They are the cases in which several erosions may be found, and in which cell infiltration or even bacterial invasion is present. Such cases belong really to the category of cases of acute ulcerative gastritis.

Differential Diagnosis. — Hæmoptysis naturally suggests itself as the first condition from which the gastric hemorrhage is to be distinguished. The existence of cough or its association with the bleeding will aid in the differentiation. The blood is often frothy from air admixture; and unless blood has been swallowed, as in sleep, the raising of large clots point to the stomach. Of course, the recognition of acute or chronic pulmonary tuberculosis, and the presence or absence of pleural congestion with its friction sound, and representing the early stage of tuberculous pleurisy, must be determined. Rarely, except in advanced phthisis, are hemorrhages of such great extent as in these uncommon cases of gastric hemorrhage.

The differential diagnosis from a commencing rupture of aortic or rupture of miliary aneurism should be thought of. From varicose gastric or œsophageal arteries in connection with cirrhosis of the liver the diagnosis is made by the clinical history, together with the recognition of a cirrhotic liver and a large spleen. In cancer and chronic ulcer, from which the actual superficial ulceration is to be differentiated, we have a history of a long existing condition and the well-known symptoms and signs, which I need not here rehearse. Even in obscure cases of cancer or chronic ulcer we always have a history of more or less impairment of health, lasting months or years, whereas in these cases the history is at most one of a few days or weeks.

Diagnosis.—The hemorrhage, its large amount, and the fact that we have excluded all other sources than the stomach, with or without accompanying or immediately preceding nausea, gastric pain, and vomiting, constitute the main elements of diagnosis, and appear to have been sufficient in a considerable number of cases for making the diagnosis, which was confirmed in all but a few instances at the autopsy.

To diagnosticate either the size of the eroded vessel or the exact locality of the ulceration is an impossibility. The difficulty of finding the ulceration at the operation, even at autopsy, may be here again repeated, and only the most careful search and inversion of the entire mucous membrane and drying off of the mucus on its surface enable us to recognize it.

Prognosis.—The prognosis in these cases is exceed-

[3] Soc. Méd. des Hôpitaux, 1893, séance December 23d.

ingly grave. It may be of interest to introduce the statistics of Savariaud, of hemorrhage in the various forms of gastric ulcer. "In fifty cases in which hemorrhage was the cause of death and in which autopsies were made, in one-fourth death was sudden by an overwhelming bleeding, in a second one-fourth it occurred within twenty-four to thirty-six hours after the first hemorrhage, in the third at the end of a week, and in the last one-fourth at the end of a fortnight." Savariaud also points out that even in erosion of the splenic artery immediate death does not necessarily follow, for in seven of seventeen cases the patient survived from two to fifteen days.

Treatment.—Medical. After a single large hemorrhage, and until repetition of the hemorrhage has occurred and a count of red blood globules shows a serious diminution in their number, medical treatment should at least be tried. This should consist of absolute physical rest to body and stomach, the patient being put to bed on his back and alimentation being exclusively rectal for three or four weeks. An ice-bag may be applied to the stomach, while nothing, not even water, should be given by the mouth, in order to avoid all gastric peristalsis. Maragliano kept a patient alive for ninety-four days on rectal alimentation, with a loss of only about five pounds in weight. Medication of ergotin, etc., should be given either by rectum or, better still, hypodermically. Intravenous or subcutaneous injections of serum should be used. Professor Dieulafoy recommends 8 gm. of chloride of sodium and 10 cgm. of nitrobenzoate of caffeine added to one litre of distilled water. Melassez advises 7 gm. of chloride of sodium to one litre of water, and Hayem 5 gm. of chloride of sodium and 10 gm. of sulphate of sodium to one litre of water.

Surgical Treatment.—In view of the fact that the first hemorrhage may by continuation be fatal, or that the second may prove so, surgical interference should be thought of and preparations for immediate operation should always be made. In similar manner serum injections should always be resorted to, although no reliance should be placed upon them alone to save life. That an operation should be performed is always difficult to decide, for patients recover even when the blood count goes below one and a half million. If a patient have lost a half to one litre of blood upon several occasions within twenty-four hours, he is certainly in danger if not operated on; so that while the amount of blood lost is our best indication, all clinical signs and symptoms should be considered. The method of procedure of Dr. Cazin, as applied to the case of Professor Dieulafoy, promises the best result, and the inversion of the gastric mucous membrane, careful absorption of the mucus by means of sterilized gauze, and a minute search with a pocket lens for the seat of ulceration should be made.

In determining the prognosis of operation, that of chronic ulcer should not be considered with acute ulceration, for the unhealthy conditions of the gastric mucous membrane, the adhesions to surrounding tissues, and the fact that the chronic ulcer involves all the gastric layers, make the prognosis more serious. Were the diagnosis promptly made, and the ulceration found at the operation and the latter be timely, the prognosis ought to be good.

I append, for the benefit of surgical readers, a list of all surgical interventions for gastric hemorrhages which bear in part, or to a greater extent, upon the consideration of surgical operation for the condition here specially considered and for chronic ulcer. *Archiv f. klin. TREATMENT OF ACUTE SERO-FIBRINOUS PLEURISY.[1]

BY CHARLES E. NAMMACK, M.D.,

PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN, BELLEVUE HOSPITAL, NEW YORK.

To tap, or not to tap, that is the question. Whether 'tis better that the patient should suffer the pressure and discomfort of abundant effusion, or to take the aspirator against the sea of sero-fibrin, and by evacuating end them? To puncture—to withdraw—no more; and by this step to say we end the heart-displacement and the other dangers that effusion gives birth to, 'tis a consummation devoutly to be wished.

But do we end them? Ay, there's the rub.

For in that aspirator what germs may come, when we have not asepticized this metal tube, must give us pause. There's the microbe that makes calamity of so long life. For who would bear the pains and weight of pleurisy, the compressed lung, the heart's crowding, the pangs of shortened breath, absorption's delay, the sluggishness of lymphatics, and the dangers that patient endurance of the effusion takes, when he himself might its quietus make with a bare bodkin? Who'd these perils bear, to grunt and sweat under a weary life, but that the dread of something after tapping puzzles the will, and makes us rather bear those ills we have than fly to others that we know not of?

Twenty-five years ago the picture here drawn would have fairly represented the mental attitude of the physician. In the late seventies Austin Flint taught us that the means to be employed for the removal of sero-fibrinous effusion were hydragogue purgatives, diuretics, blisters, and the use of certain remedies which have been supposed to act directly as sorbefacients. Only in cases in which the liquid had accumulated sufficiently to endanger life was aspiration advised, that procedure being reserved for chronic pleuritis,

[1] Read before the section on medicine, New York Academy of Medicine, February 19, 1901.

which was stated to be a much more frequent affection than the acute. In the summer of 1880 there were two cases in the medical wards of the New York Hospital in which repeated aspirations had been done, and in which the fluid had undergone change from a serofibrinous to a purulent exudate. My notes include the statement of the visiting physician, that "chest tapping in adults is a good operation for one or two times when the accumulation is dangerous, but repeated tapping converts a pleurisy with effusion into an empyema. Why this is so I do not know, but my experience proves it." At the present time two explanations, other than tapping, would rise to explain this conversion. It must be remembered that those were the days when asepsis was just dawning.

With the advances in medical knowledge and equipment of the last twenty years, this timidity has been thrown—perhaps too far—to the winds. The confidence engendered by aseptic principles has made of chest-tapping a simple and safe operation, and it is resorted to readily, and sometimes needlessly. Given a diagnosis of pleurisy with effusion, and aspiration follows, as a matter of course, in the practice of many. It is well, however, not to promise removal of fluid to a patient until exploratory puncture has actually demonstrated the presence of fluid and its character. While a typical pleuritic effusion gives other physical signs which may be relied upon with great certitude, all cases do not follow the typical text-book course, and embarrassment may follow failure to withdraw fluid which had been confidently predicted. In a recent case the clinical history, the ordinary signs by palpation, percussion, and auscultation, together with a leucocyte count of 34,000, all seemed to point conclusively to empyema following pneumonia, yet repeated exploratory punctures were negative.

At bedside clinics in Bellevue Hospital I have been in the habit of teaching that chest-tapping should be performed in sero-fibrinous pleurisy for three indications: First, when life is directly threatened, or endangered by asphyxia from compression, or by cardiac weakness; second, when fluid has risen to the third interspace in front, since experience has shown that effusions of this size rarely disappear spontaneously; third, in all lesser effusions when spontaneous absorption is unduly delayed. When none of these indications is present, the medicinal treatment of the case is studied. This includes the local application of guaiacol, or of iodine when the effect of guaiacol on the heat-regulating and vaso-motor centres is too pronounced; internally, mild catharsis by sulphate of magnesium in concentrated solution, with limitation of the ingested liquids to as low a point as possible, and the consumption of as much table salt as the patient can be induced to take. Whenever opportunity affords, cases of moderate effusion are treated, side by side, by this plan and by tapping. Our experience would seem to warrant the assertion that progress is more rapid in the cases not tapped.

This paper, however, is not written as a protest against tapping. Tapping removes in a few minutes what nature might require days or weeks to absorb. But the two processes are not identical. Tapping does not cure the underlying causative condition of a pleuritic effusion, be this tuberculous, pneumococcal, streptococcal, toxæmic, or otherwise. Neither does it allow time for those reparative changes in the serous cavity by which reaccumulation of fluid is prevented. Whether we can, in connection with tapping, determine an exudative and reparative inflammation, by the injection of fluids such as methylene blue, as advocated by Charles H. Lewis,[1] is a point of great interest and warrants further study.

On the other hand, the longer nature's efforts at absorption are delayed, the more futile they are likely to be. In protracted cases, pathological changes in the pleura occur, by means of which its absorbent properties become impaired and the mouths of the lymphatics become obstructed. It is difficult to set time limits arbitrarily. Each case must be judged for itself. In general, however, an effusion which has remained stationary for longer than seven days should be partly evacuated by aspiration. It is sometimes surprising to witness the prompt absorption that will follow the withdrawal of a fractional part of a large effusion, which had previously manifested no tendency to diminish. This occurred in three of my own cases in which, after exploratory puncture had been made, further tapping had been refused by the patients.

In the foregoing remarks I have considered only the pathological indication for treatment in a case of pleurisy; namely, the effusion. Of course there are additional etiological indications. It would be as irrational to treat all kinds of sore throat on one principle as to deal with all pleurisies alike, irrespective of their causation. Therefore the underlying tuberculosis, rheumatism, acute infection, septic process, local or general, new growth, gout, Bright's disease, traumatism, or other cause, must each receive its separate consideration. Similarly, symptomatic indications must be met, as they arise, by appropriate treatment, and complications, such as cardiac failure and pulmonary œdema, must be forestalled by attention to rest, and to the rules for paracentesis, and by other necessary steps founded on knowledge of the course of the disease.

During convalescence, in addition to the restoration of bodily health and strength on the principles usual after acute disease, the indications are: first, to protect the patient particularly against chill, by clothing and mild climate; second, to provide respiratory exercises, and, if possible, mountain air, for the re-expansion of the lungs and chest; third, to prevent pulmonary tuberculosis, the remote development of which should be borne in mind, notwithstanding the apparently successful issue of the pleurisy.

42 East Twenty-ninth Street.

[1] Medical Record, December 30, 1899

Renal Echinococcus.—Ludwig Stein (*Wiener klinische Wochenschrift*, October 25, 1900) concludes that the surgical treatment of renal echinococcus comprises nephrectomy as well as the mere opening of the sac and subsequent drainage; which method is to be chosen, can be determined only at the time of operation, first, after the definite diagnosis has been established; and secondly, after it has been determined how much if any kidney substance is left for the performance of the renal functions. The abdominal route often offers the only way of arriving at positive conclusions. If after abdominal incision it appears that the case is one for incision and drainage, the peritoneal wound is closed and an extraperitoneal lumbar operation performed.

Influence of Chloroform Narcosis upon the Uterine Contractions during Physiological Labor.—Westermark (*Archiv f. Gynäkologie*, 1900, Bd. 61) concludes: (1) Complete chloroform narcosis diminishes the frequency of the pains. (2) Complete narcosis increases the interval between the pains. (3) Complete narcosis has no influence upon the intra-uterine pressure during the interval between the pains. (4) Complete chloroform narcosis diminishes the duration of the pains. (5) On account of the complete narcosis, the intra-uterine pressure sinks during the pains, but rises again after the discontinuance of narcosis. (6) During complete narcosis the pain curve reaches its height

in about the same time as before narcosis. (7) The rapidity of the increase in the pain curve during complete narcosis to that before narcosis is as 3.4 : 4.3. The fall of the curve occurs in both instances with about the same rapidity (2.4 : 2.5). (8) The obstetrical chloroform narcosis diminishes the frequency of the pains. (9) The obstetrical narcosis lengthens the interval between the pains. (10) The obstetrical chloroform narcosis has no influence upon the intra-uterine pressure during the interval between the pains. (11) The obstetrical narcosis diminishes to a great degree the uterine pains. (12) The obstetrical chloroform narcosis diminishes to a slight degree the duration of the pains. (13) The intra-uterine pressure during the pains is not influenced to any material degree by obstetrical chloroform narcosis. (14) During obstetrical chloroform narcosis the pain curve reaches its acme in about the same time as before the narcosis. (15) The rapidity of the rise in the pain curve during obstetrical narcosis to that before narcosis is as 4 : 3.7. The rapidity of the fall during obstetrical narcosis to that before narcosis is as 2.7 : 2.4. Thus, during a normal labor complete narcosis, even apart from its general dangers, is distinctly contraindicated, in that it slows delivery to a marked degree. The obstetrical narcosis diminishes the frequency of the pains, without materially influencing the intra-uterine pressure or the duration of the pains.

Ligature of the Blood-Vessels of the Hilum of the Kidney.—Raffaello Giani concludes that ligature of the renal vein produces stasis with disturbed nutrition of the renal parenchyma, and sometimes small areas of complete necrosis. The collateral circulation soon becomes established, with more or less relief to the condition of the parts. The *restitutio ad integrum* of the parenchyma being usually satisfactory after ligature of the renal vein, it follows that in lesions of this vein the surgeon should ligate it, and limit his ligature to it.—*Lo Sperimentale*, Anno liv., No. vi.

The Implantation of Thiersch Skin Grafts for the Cure of Severe Stenoses of the Larynx and Trachea.—H. Alapy reports a case in which by applying the method first described by Gersuny he was able to relieve completely a high degree of post-diphtheritic laryngeal stenosis. The patient, a child of four, had already been intubated and subsequently tracheotomized owing to the contraction of the cicatricial tissue which finally did not permit the introduction of even the smallest intubation tube. A preliminary laying open of the larynx revealed an almost impassable stricture which did not yield to attempts at dilatation by means of a silk thread carried through the tracheotomy wound and nostril, for although instruments of moderate calibre could finally be passed, even after several months of this treatment respiration was impossible except through the tracheotomy tube. At the second operation the larynx and trachea were split open, the cicatricial tissue was excised, and a skin graft from the thigh, rolled upon a cylinder of gauze with the cut surface outward, was sutured into the circular defect. Eight days later the tampon was removed and the wound closed, and the use of the intubation tube resumed. Finally, eighteen months after admission, the patient was discharged with all fistulæ fully healed and able to speak with a somewhat hoarse but perfectly audible voice.—*Centralblatt für Chirurgie*, December 29, 1900.

Etiology of Acute Rheumatism.—J. W. Springthorpe enumerates four factors which enter into the etiology of acute rheumatism. These are: (*a*) Food proteid of a certain amount and nature; (*b*) an inherited or acquired tendency in duodenal and hepatic metamorphoses to form therefrom pathological irritants, instead of normal pabulum and physiological stimuli; (*c*) exposure of the more or less fatigued body to humidity and atmospheric variations of a certain duration and intensity; and (*d*) the chance thus offered to certain of the intestinal flora to become pathogenic and produce toxins, or, it may be, themselves to circulate in the blood. Suitable combinations of these four variants offer, in the author's opinion, a satisfactory explanation of attacks of rheumatic fever. And in support of this theory he quotes the effect, which he has often noted, of an attack of influenza. Whether the gastro-intestinal form of influenza be or be not due to the presence of Pfeiffer's bacillus in the duodenum he cannot say, but let that form of the disease attack an individual of hepatic temperament, and we have generally a fever either actually rheumatic or with difficulty distinguishable therefrom.—*Intercolonial Medical Journal of Australasia*, November 20, 1900.

Infantile Laryngitis.—Brindel says that there is a form of tuberculosis affecting the larynx of infants and assuming an ulcero-œdematous type. It is always fatal and death comes on rapidly, this rapidity being determined by age, condition of the lungs, and respiratory embarrassment depending on the amount of laryngeal stenosis. He believes that tuberculosis may attack the upper air passages primarily and that it causes intense dysphagia and early vocal troubles. Such symptoms in children should lead us to suspect this form of laryngeal invasion.—*Revue Hebdomadaire de Laryngologie*, October 13, 1900.

Pleuritic Urticaria.—R. Gomez reports a case of this affection, which, while rare, does sometimes make its appearance toward the end of the pleurisy, at the period of absorption of the exudation. The eruption occurs most frequently on the trunk, abdomen, and anal region, and may be most abundant. The early appearance of urticaria is a favorable symptom, pointing, according to Carageargiadès, to a rapid cure of the pleurisy, while its tardy appearance in scanty amount indicates a long convalescence, and possibly tuberculosis. This authority considers the eruption due to the direct action of the toxins in the pleuritic exudate which are thrown into the lymphatic circulation during the absorption process.—*La Riforma Medica*, December 27, 1900.

Cardioptosis.—G. Rummo says that the heart may undergo ptosis from several causes. 1. Increase of size and weight. Yet there are cases of hypertrophy without cardioptosis. 2. From variations in the endothoracic and endoabdominal pressure. If a right pleurisy increases the thoracic pressure on the right, the heart will be displaced to the left. If atelectasis of the right lung diminishes pressure, the heart will go to the right. 3. Impaired tonicity. The only treatment consists in the application of some apparatus or bandage to support the diaphragm and in the administration of arterial tonics, such as ergot, hydrastis canadensis, or nux vomica.—*La Riforma Medica*, December 28, 1900.

Neurasthenia of Otic Origin.—Guiseppe Mendini reports the case of a man of forty years, in good health, who suddenly began to suffer from a sense of heaviness in the head, headache, weakening of memory, impaired vision, insomnia, and vertigo. The etiology was at first obscure, but it was finally found that there was a concavity of the left membrana tympani. Various remedies failing to bring relief, it was decided to perform tenotomy of the tensor tympani. This was done under cocaine. The immediate after-effects were vertigo and unconsciousness, but rest in bed and the administra-

tion of a calming potion overcame these. Eight days later a slight mobility of the membrana tympani when the nose was blown was all that remained of the traumatism, while the symptoms of neurasthenia had entirely disappeared.—*Giornale Medico di Regio Esercito*, December 31, 1900.

Massive Hepatic Cancer.—Virgilio Bolli concludes that the symptoms found in the majority of cases of primary cancer of the liver are identical with those of many other diseases of that organ, a fact which greatly obscures the diagnosis. The intestinal disturbances, the inconstant pain, hypocholia, and fever are certainly not pathognomonic. The hypertrophy of the liver and progressive cachexia are in truth the only symptoms upon which we can base a diagnosis. The author reports a case of *cancer massif* in which even the hypertrophy was lacking.—*La Riforma Medica*, January 26–28, 1901.

A Note on the Early Treatment of the Early Stages of Acne Rosacea, with Special Reference to the Use of Suprarenal Gland Extract Therein.—William J. Munro divides the treatment of this affection into two parts: 1. Measures calculated to remove any general or systemic cause; 2. Those used to remedy the local lesions. All disturbances of the digestive tract must be removed. The patient's own idiosyncrasies must be studied. Regular exercise should be recommended. The bowels must be regulated. Internal antiseptics hold an important place in the treatment. Any gouty tendency must be corrected. Gynæcological troubles should be looked after. The objects of external treatment are: (1) To remove all effects of secondary infection, and prevent its recurrence; (2) to counteract the local capillary inertia, and the resulting tendency to blood stasis. The writer has used a paint consisting of a preparation of suprarenal extract, dissolved in ʒ i. of sterilized water, with a small crystal of thymol added to prevent decomposition. This was applied to the face each night after hot bathing. In the morning a precipitated-sulphur and zinc-oxide lotion was used. The internal administration of the suprarenal extract materially helped the local measures.—*The Australasian Medical Gazette*, December 20, 1900.

Spongifying the Labyrinth.—J. Hollinger advocates the use of this clinical phrase, and states that the process usually starts at about eighteen to twenty or twenty-three years of age. The increase of the deafness is either slow and steady, or at times there are sudden turns for the worse, or finally there are cases in which the deafness sets in suddenly. At the age of twenty-eight to thirty the condition is usually fully developed, and remains unchanged often to the oldest age. Some patients may then have so much hearing left that they can follow a conversation, others a loud conversation, others may be "stone" deaf. It often seemed that those cases which were treated most persistently showed finally the worst function. Whether rest, away from the noise of the great city, will not benefit the patient more than pneumo-massage and Politzer bag, catheter and pressure probe, will have to be decided in future by very careful and persistent functional tests. He comes to the following conclusions: First. Sclerosis and similar words to indicate this disease of the ear are without meaning, pathologically or clinically. Second. Spongifying of the labyrinth is a well-defined disease, clinically and pathologically. Third. The diagnosis can be made in the living in a comparatively early state, from the history and the trio of functional tests: (*a*) Short or negative Rinné. (*b*) Increase in hearing of low sounds (A) by bone conduction. (*c*) A large part, one to several octaves, of the lowest sounds cannot be heard by air conduction. Fourth. The prognosis as to life is good; as to recovery of hearing bad. Fifth. The treatment must be applied very judiciously. We can judge of and compare the effect of a treatment in a given disease only when we are able to make an absolute diagnosis of the disease. Patients who have been treated from the start of the disease are often, after years, in a worse condition as to their hearing than others who have been left alone.—*Laryngoscope*, January, 1901.

The Histological Changes in the Kidneys from Corrosive-Sublimate Poisoning.—B. Vasoin from experimental researches concludes that even less than 1 cgm. of corrosive sublimate will produce degeneration and necrosis of the epithelium in the uriniferous tubules of rabbits. This is in the case of slower poisoning. When the mercury is administered subcutaneously, there are merely diffuse hemorrhages, and detachment of the epithelium.—*La Riforma Medica*, January 18–20, 1901.

Rheumatic Fever in Relation to the Throat.—St. Clair Thompson says that the present state of our knowledge on the relation of tonsillar affections to rheumatism may be summarized as follows: 1. It is undoubted that a certain number of cases of acute rheumatism are preceded by an angina in a proportion varying from thirty to eighty per cent. 2. Both rheumatism and angina have many etiological points in common—season of year, cold, wet, fatigue, depression, vitiated air, etc. 3. The connection of angina and rheumatism, though undoubted in a number of cases, is not yet clearly established. 4. The tonsil may be the port of entry of the rheumatic virus, and this even although the naked-eye appearance of the throat gives no indication of its being affected. 5. The particular affection of the throat which is associated with rheumatism is not yet established. Apparently it is not peritonsillar abscess (quinsy). 6. Peritonsillar inflammation does not appear to be arrested by the administration of anti-rheumatic remedies. Many cases of parenchymatous and lacunar tonsillitis, on the contrary, are considerably benefited by the administration of salicin or salicylate of sodium. That this action proves the rheumatic nature of the disease cannot yet be accepted. 7. The question requires further research in two directions: one in differentiating the various forms of angina, and settling the one which is associated with rheumatism; the other in further research to discover the true nature of rheumatism.—*Laryngoscope*, January, 1901.

Vesical Hemorrhage during Labor.—George A. Brown reports this case of a woman aged forty-six years, multipara, who has had eleven children and after each labor has had some complication, usually post-partum hemorrhage. On December 5th, a day or two before the last labor, the patient had a fall. During labor the pains were irregular and had a peculiar tearing character, as if her bladder were being dragged out of her. After the pain became regular there was no progress, as the pressure of the breech came on the anterior vaginal wall. The vaginal examination was rather puzzling, as the anterior vaginal wall descended into the vaginal passage just like a large tumor. After the os was dilated—the patient was kept in the knee-and-chest position until this occurred—the child was extracted in the usual way. Before the birth of the child, as well as afterward, the patient was catheterized and dark bloody urine was withdrawn. The patient also passed some small clots. She was given urotropin gr. ss. three times a day. On December 11th the urine was normal.—*Montreal Medical Journal*, January, 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 9, 1901.

THE NEW MEDICAL BILL FOR NEW YORK STATE.

THE measure now before the legislature of the State of New York, known as the "Bell bill," which gives a definition of the practice of medicine, was introduced January 14, 1901, nearly eight weeks ago. It has been thoroughly discussed before the assembly committee on public health, and the promoters of the measure, as well as those who oppose it, have had abundant opportunity, at the three hearings which have been given, to place their arguments before the legislature and the public. They have been accorded every privilege by the chairman of the public health committee, Dr. Nelson H. Henry, of this city, to express their views, and no one can say, with any degree of fairness, that both sides have not been treated with strict impartiality. The hearing on the bill to legalize the practice of osteopathy has really been a hearing on the "Bell bill," making in all four hearings of four hours each. The members of the legislature—those who are members of the public health committee, as well as those who will have to vote on the bill if the committee reports it favorably—have devoted about sixteen hours to these public hearings. They are probably about ready to decide what, in their judgment, should be done with this vexed question. Doubtless some of the legislators—possibly all of them—have been importuned by well-wishers and constituents to vote for or against this measure, and would gladly be released from the necessity of voting either way. One cannot, however, secure release from an obligation by shirking a duty, and as the question involved in this bill is one of great importance to the community, and as the members of the legislature are as fully alive to their obligations as citizens as those of us who are not legislators, there is no doubt that they will be found, when the time arrives for the test, standing manfully at their posts, voting not as friendship or individual preference may suggest, but, as their oath of office dictates, for the benefit of the State.

To our mind, the question of how this matter should be decided resolves itself into the plain proposition: Is it necessary to have medical laws in order to protect the people from incompetent practitioners of medicine? By practitioners of medicine we mean all who make a business of treating disease.

Few if any callings necessitate greater honor, integrity, and ability on the part of their followers, than that of the healing art. This has been so admirably expressed in an opinion handed down by the Pennsylvania courts that we quote from it as follows: "The experience of the past has justified the wisdom and necessity of medical laws. There is no time, perhaps, in the experience of life that persons are more susceptible to imposition than when sick or in failing health. They are ever as ready to catch at straws as is a drowning man. The profession that involves the price or value of human life demands of its practitioners a high degree of education in all its branches, and such a degree of honor and character as enables them fully to appreciate the important and confidential relations they sustain to their patients, and who possess the highest estimate of human life and the good health of society."

This being so, is there any reason why one class of practitioners should pass an examination more rigid than another class, or that any class should be allowed to enter upon the practice of so important a calling—one dealing with human life, human health, human honor—without any examination, simply because they practise some peculiar method, under some mystifying or unusual name?

It is not easy to gain the right to practise medicine in the State of New York, if one desires to do it intelligently and honorably. If one is willing, however, to waive honor, and to restrict one's self to some peculiar method, like the so-called method of osteopathy, then it is very simple to come to this great State, and possibly without moral character, possibly without knowledge of bacteriology, etiology, and pathology, settle down and practise unmolested. These people who practise under these peculiar names possess no knowledge which educated physicians do not possess. Whatever is known of disease, its causes, manifestations, and treatment, is taught in every medical college. The peculiar effects of the mind in producing physical derangements; the effects of massage and manipulations; the therapeutic value of water—all these are known and taught in medical colleges, and practised by educated physicians. The practitioner who holds himself out as competent to treat disease by the exclusive use of any of these methods does so because he sees in this course a way to evade the law. And this is all there is to be said on the question. If the medical laws are necessary for the proper protection of the public health, then they are just laws, and, being just, should include all who hold themselves out as being able to heal or to treat disease, no matter what method they employ. Just laws should be enforced without fear or favor.

There seems to be no doubt that the "Bell bill" is a just bill, and a needed protection to the community. We trust it will be favorably reported without delay, and become a law. If the physicians of the State of New York, seeing the necessity for the enactment of this measure, will urge their representatives in the legislature to vote for it when it leaves the committee, there will be put on the statute books, in the first year of the twentieth century, a law the good effect of which will be felt throughout the United States.

COMPULSORY EXAMINATIONS FOR OSTEOPATHS AND CHRISTIAN SCIENTISTS.

We are glad to note that the so-called Bell bill which, if passed, will compel all who wish to practise medicine to pass the State examination, is to be reported favorably by the committee before whom the hearings have been held. As we have previously pointed out (Medical Record, February 2d), the amendment provided by this law will compel those who wish to pose as practitioners of "osteopathy" and "Christian science" to submit to the same regulations as are enforced in the case of the graduate of the regular medical school, in order to carry out their intention of practising. The fairness of such a requirement, it would seem, should be evident to any one, since the claim that these unlicensed persons wish to treat only certain diseased conditions is ridiculous and not founded on fact; but the inability of the non-professional and non-scientific mind to appreciate this is well illustrated by the views of Mark Twain given, during the last few days before a committee of the legislature, in favor of legalizing "osteopathy." When a man of Mark Twain's age, experience, and reputation can be induced, through ignorance of a subject and an illogical mental attitude—the fallacies in which are clear to any one who thinks an instant—to support such a measure, it is quite time that the absurdities and dangers of removing legal restrictions from those who wish to avoid responsibility by adopting meaningless or deceptive names should be pointed out with emphasis. The passage of the Bell bill will insure equal treatment before the law of all who wish to assume the responsibility of caring for the sick and injured. The medical profession of this State ought to appreciate the importance of this measure, and we again urge physicians in all parts of the State to write in favor of this bill to their assemblymen and State senators, not merely to the chairman of the committee on public health. We may be sure that the legislators will be flooded, from now until the bill is voted upon, with those peculiar effusions which pass for statements of fact among the foolish knaves and knavish fools who compose the "sects" of "osteopaths" and "Christian scientists."

SOME OF THE COLLATERAL SYMPTOMS OF FACIAL PARALYSIS.

While it is known that paralysis of the muscles supplied by the facial nerve is sometimes attended with loss of the sense of taste upon the anterior third of the tongue, the pathway of the gustatory fibres to the brain is still a matter of discussion. Nor have the relations of the facial nerve to the secretion of saliva, of sweat, and of tears, as well as to the sense of hearing, been thoroughly worked out. Finally, the chronological order in which the symptoms appear and disappear has not heretofore been described in detail. With the object of clearing up some of the doubtful points connected with this subject, Köster (*Deutsches Archiv für klinische Medicin*, Bd. 68, Hft. 3, 4, 5, 6) made an extensive clinical and experimental study of the electric irritability, of the motility of the uvula and the soft palate, of the sense of taste, of the sensibility of the tongue, and of the secretion of sweat, saliva, and tears. Forty-one cases of facial paralysis were studied for this purpose, the lesions being situated at various parts of the nerve between its origin in the brain and the periphery, and dependent upon disease, traumatism, or operation.

It was found, as had previously been pointed out, that interference with sweating on the affected side took place only when the facial paralysis was peripheral or nuclear, and not when it was supranuclear or cortical. The alterations consisted not only in postponement of onset, but also in diminution in amount. It was not found, as has been contended by others, that the derangement in sweating bore any direct relation to the electric reactions. It developed, on the other hand, that in a small proportion of cases hyperidrosis was present on the paralyzed side, especially in recent cases, without direct relation to the electric reactions. The abnormality in sweating, in both time and amount, gradually disappeared as the paralysis subsided; but here again there was no direct relation to the electric reactions. In fact, in ten of fourteen cases sweating returned before the change in electric reactions disappeared. In view of the facts, the diminution in sweating is attributed to a paralytic state and the hyperidrosis to an irritative state of the excito-sudoral fibres, which possess a distribution independent of the remaining nerve fibres. From the general want of relation between the disturbance in sweating and the electric reactions, it is believed that the excito-sudoral fibres of the facial nerve degenerate more rapidly than the motor fibres, though, of course, both may undergo this change synchronously. The rapid disappearance of the derangement of sweating is thought to justify the assumption of collateral innervation on the part of the trigeminus.

Derangement in the sense of taste was observed in twenty-four cases, and in nine of these it was associated with morbid alteration in the secretion of saliva. In seven of the latter the secretion was diminished or abolished upon the affected side. In three cases increased secretion of saliva on the paralyzed side was present, and might have been thought to be of paralytic origin, although the possibility of the abolition of inhibitory function must be taken into consideration. The coincidence of increased secretion of saliva with partial disturbance in the sense of taste indicates that the lesion was a slight and in part an irritative one. In only two cases did the alteration in the secretion of saliva subside at the same time as that in sweating, while in three it occurred later. In one case the derangement in salivary secretion disappeared earlier than that in taste, in one case simultaneously, and in three cases later. In one case the derangement in salivary secretion disappeared simultaneously with that in electric irritability, while in four cases it occurred earlier. It would appear as if the fibres governing the secretion of saliva are less sensitive and when injured are better capable of regeneration than the motor fibres of the facial nerve. There seems, further, no doubt that the chorda tympani nerve contains gustatory fibres which it con-

veys to the seventh nerve. In view of the varying distribution upon the tongue of taste sensibility due to fibres from the fifth nerve through the chorda tympani, and of the return of the taste sense upon the anterior portion of the tongue after its loss, following injury to or destruction of the Gasserian ganglion or of the chorda tympani nerve, the conclusion is reached that the glossopharyngeal nerve is capable of collateral innervation of the tongue.

Trophic and sensory changes were not observed. Nor was it found that the position of the uvula bore any relation to the state of the palatal muscles, which themselves did not suffer as a result of facial paralysis. Derangement of hearing, on the other hand, was relatively common, being observed in fifteen among twenty-four cases. Buzzing, roaring, or rumbling in the ears, slight impairment of hearing, and increase of pre-existing impairment of hearing were the usual complaints. The lesion under these conditions is situated in the vicinity of the geniculate ganglion, so that the presence or absence of impairment of hearing of nervous origin is a guide in the localizing diagnosis of facial palsy.

In a number of instances derangement in the secretion of tears was observed in association with facial paralysis; and the absence of any such derangement, in the presence of an intact geniculate ganglion, and the invariable association of such derangement with a lesion of the auditory nerve and central deafness, are indicative of its dependence upon a lesion in the vicinity of the geniculate ganglion. The secretion of tears on the paralyzed side was totally absent in twelve of twenty-five cases, and distinctly diminished in eight, while in five it was greatly increased. The last is believed to be due to irritation of tear-secretory fibres. Of thirteen cases in which the relation between the secretion of tears and the remaining symptoms was studied, lacrymation reappeared simultaneously with perspiration in six, while in seven the former appeared later. In seven cases electric irritability returned later than the secretion of tears, while in four both reappeared together. Cessation of lacrymation and of disturbance in the sense of taste subsided simultaneously in four cases, while in three lacrymation returned earlier and in five later than the sense of taste. Of thirteen cases attended with derangement in lacrymation derangement in the secretion of saliva also was present in seven. In two of the latter the secretion of tears and the secretion of saliva returned simultaneously, while in four the latter reappeared the earlier.

To recapitulate: Of the symptoms associated with paralysis of the muscles supplied by the facial nerve, disorder in hearing disappears first, apart, of course, from caries of the petrous bone. Then follows derangement in the secretion of sweat, together with, or shortly succeeded by, derangement in the sense of taste. Generally the secretion of saliva returns later, and not rarely the secretion of tears still later. Restoration of the normal electric irritability of the motor fibres occurs last, after preceding return of voluntary irritability.

From the foregoing considerations the conclusion seems justified that the absence of all other loss of function except the derangement in sweating and the presence of motor palsy is indicative of the peripheral seat of a facial palsy below the stylomastoid foramen and up to the giving off of the chorda tympani nerve. If the interruption in continuity is situated at any point above the giving off of the chorda tympani, either in the last descending portion or in that passing in the Fallopian canal over the tympanum, there will be, in addition to motor and sudoriferous disturbance, derangement in the sense of taste and often also in the secretion of saliva. If the lesion involves the vicinity of the geniculate ganglion, there will constantly be, in addition, derangement in the secretion of tears and at times disturbance in the sense of hearing, due to a lesion of the auditory nerve. If the morbid process is situated between the geniculate ganglion and the superficial origin of the facial nerve, the foregoing symptoms will be present, except the loss of the sense of taste. When the lesion involves the facial nucleus and the immediate neighborhood, the symptoms will be the same as those mentioned last, and the diagnosis will have to be based upon the presence of other symptoms indicative of bulbar disease. Lesions involving the facial nucleus alone, at least if dependent upon congenital defects in the motor nucleus of the facial nerve, are attended with derangement in sweating in addition to motor palsy.

Experiments on animals confirmed the impression gained from clinico-pathological observation, that the secretory fibres of the submaxillary and sublingual glands pass out with the trunk of the facial nerve. While the excito-secretory fibres for the lacrymal gland in man appear to pass in the facial nerve, they do not in animals, and this function must, therefore, be subserved by either the sympathetic or the trigeminus. In cats and dogs it is probably subserved by the sympathetic. Absence of degeneration in the lacrymal nerve was found after destruction of the facial nerve at the geniculate ganglion in apes, and this fact is indicative of a difference in the secretory innervation of the lacrymal gland between these animals and man.

News of the Week.

Shortening the Medical Course at the University of Pennsylvania.—Provost Harrison of the University of Pennsylvania, in his annual report recently published, has announced a readjustment of the studies required of students for the degree of doctor of medicine, by which they may complete the course in arts or science and get the medical degree in seven years. By pursuing the plan outlined, the course in medicine is made three instead of four years. The plan provides that, under certain conditions, a senior in college may be a freshman in the medical school.

A Defiance of Quarantine.—During the past two weeks a Yale student, who was suffering from diphtheria and who was quarantined in his room by the board of health of New Haven, was removed by his mother and taken home to Kingston, N. Y. It seems as if

force would have been justified in preventing such an outrage on the community. We do not imagine that the residents of Kingston will enjoy the importation of diphtheria.

Mrs. Eddy on Vaccination.—The following letter from the high priestess of Christian science, Mrs. Mary B. G. Eddy, recently published, bears witness to the general belief that she at least is not a dupe of "Mother Eddy": "On the subject of reporting contagion, I have this to say: I have always believed that Christian scientists should be law-abiding, and actuated by this conviction I authorized the following statement, which appeared in the Boston *Herald* about one year ago: 'Rather than quarrel over vaccination, I recommend that, if the law demand an individual to submit to this process, he obey the law and then appeal to the gospel to save him from any bad results. Whatever changes belong to this century, or any epoch, we may safely submit to the providence of God, to common justice, individual rights, and governmental usages.' This statement should be so interpreted as to apply, on the basis of Christian science, to the reporting of contagion to the proper authorities when the law so requires. When Jesus was questioned about obeying the human law, he declared: 'Render unto Cæsar the things which are Cæsar's,' even while you 'render unto God the things which are God's.'

"Mary Baker G. Eddy."

The Tuberculin Test for Cattle.—The tuberculosis committee of the State board of health reports tuberculin testing of 3,247 head of cattle last year. Of this number, 184 were condemned and 142 destroyed. Awards amounting to $1,428 were made to sixty-four owners of cattle destroyed. The State board says that the report of the special legislative committee submitted to the legislature last year on tuberculosis and other animal diseases did much harm among the farmers and breeders, inasmuch as it apparently disapproved of the policy and teaching of the State board, which has insisted that all tuberculin-reacting animals should be separated, quarantined, and destroyed. "While to some minds it may seem impossible," says the board, "that bovine tuberculosis can ever be entirely eradicated from our dairy herds, because of reinfection by human attendants, new additions of diseased cattle to the herd, or from other sources, yet we maintain that constant vigilance will ultimately secure immunity, and those who will carefully apply the tuberculin test from time to time in conjunction with other methods of detecting tuberculosis, and promptly separate and dispose of all the reacting animals in a safe and legitimate manner, may practically and permanently clear their dairy herds of the disease. We strongly maintain that the better policy for the State is to expend an adequate amount of its funds for educating the farmer in the most approved methods of eradicating tuberculosis from herds, thoroughly and completely examining and testing them when necessary, and also instructing our local health authorities in the best methods of enforcing sanitary rules and regulations in all our dairy stables."

First Aid to the Injured.—The annual meeting of the Society for Instruction in First Aid to the Injured was held on Friday, February 22d, in the United Charities Building. The annual report, which was ready by President Charles H. Marshall, showed that over thirteen thousand persons had been instructed by the society since its beginning. The society instructs policemen, firemen, and railroad men.

Report upon Arsenic in Beer in Great Britain.—The London *Hospital*, February 16th, says: "The interesting report upon arsenic in beer, made to the local government board by Dr. Buchanan, has now been published. His investigations establish beyond question the presence of a large proportion of arsenic in the sulphuric acid used in the preparation of glucose or brewery sugar. He expresses himself as satisfied by the steps taken by the trade to stop the circulation of harmful beer as soon as the mischief was discovered, and further he is able to report that the tests now adopted would condemn beer containing as small a quantity as one part of arsenic in 1,500,000 parts of beer."

Smallpox Scare at Woodbury, N. J.—A paragraph in some of the New York journals on February 22d stated that Woodbury was in the midst of a smallpox scare. The report further stated that the health officers of the town had ordered all the churches, Sunday schools, and public schools closed; that all citizens had been warned not to congregate in crowds; that four thousand persons had been vaccinated within the past few days, but that only three cases of smallpox had appeared up to the time of writing. The good people of Woodbury certainly believe in preventive measures. It is stated that the Salvation Army members have tendered their services as nurses if the need arises.

Philadelphia Neurological Society.—At a stated meeting held February 25th, Dr. William H. Teller and Dr. F. X. Dercum exhibited "A Case of Astereognosis." Dr. George L. Walton and Dr. Walter E. Paul, of Boston, by invitation, read a paper entitled "Astereognosis: with Illustrative Cases." An analogy was made between the mechanism of the perception of the nature of objects through touch and that of speech on the one hand, and that of astereognosis and aphasia on the other hand. The parietal region was regarded especially as the area for stereognostic perception. At the close of the meeting a reception was tendered Dr. Walton and Dr. Paul at the University Club.

Vital Statistics of Cuba.—Surgeon W. C. Gorgas, U.S.A., reports that the number of deaths, 476, is the smallest that has occurred in any January in Havana in the last twelve years, the next lowest being that of January, 1890, when there were 486 deaths, the highest being that of January, 1897, when there were 1,556 deaths. For the twelve years there has been an average of 829 deaths. In comparing the death rate there is a still better showing. The rate for January, 22.75, is considerably less than the lowest for the past twelve years, 1894 being the next lowest, with a rate of 27.36.

In 1899, as shown by the report, we had a rate for January of 63.84, in 1900 23.90, and January, 1901, 22.74. The rate for last year was 24.40. Yellow fever has decreased from 62 to 24, and the deaths from this cause, from 20 to 7. The number of deaths is kept up by the increase among the deaths from tuberculosis, which about balances the decrease in deaths from fevers. While there has been a considerable decrease in the immigration as compared with December, it is about the same as during last January. Compared with December, the number of births is greatly decreased. This is only apparent, however, as the larger number last month was due to the fact that a great many children, born in the previous months and during the war, were registered, to comply with the law.

Roosevelt Surgeon Resigned.—Dr. Pannici, the Roosevelt Hospital surgeon who on Tuesday night, February 25th, refused to enter the Strathmore apartments after the fire there, to attend to an injured fireman, resigned on February 28th. Ill health was given as the cause, and the surgeon's friends declare that his refusal was based on that ground; being subject to rheumatism, he feared to enter the water-soaked building. The dismissal of the surgeon was ordered by the hospital governors just before he resigned.

Dr. Lewis, State Health Commissioner. — Dr. Daniel Lewis, of New York City, was nominated on March 1st by Governor Odell as State health commissioner, and his name was sent to the senate for confirmation. Dr. Lewis was president for three terms, and served since 1895, of the State board of health, which has been legislated out of office. His appointment as State health commissioner lasts until December 31, 1904. The salary is $3,500 a year. He will have sole charge of matters concerning the public health of the State, which have up to the present been supervised by the State board of health.

Smallpox on the Increase in New York City.—Little has been heard of smallpox within the past few weeks, and the general opinion seems to be that the disease is on the wane. Dr. Dillingham, of the Bureau of Contagious Diseases, however, denies that such is the case, and states that it has increased rather than diminished during the past month; and he further warns the community that vaccination should not be neglected. The *Evening Sun*, February 28th, gives the following statistics since the disease broke out on November 5th: There have been 311 cases of smallpox reported to the board of health. The number of cases for each month was as follows: November, 33 cases; December, 70 cases; January, 78 cases; and February, which is a short month, 130 cases. Forty-one of the patients died. Since November 5th, 147,526 persons were vaccinated in the borough of Manhattan by the board of health vaccinators. During the same time, in the five boroughs constituting Greater New York—Manhattan, Queens, the Bronx, Brooklyn, and Richmond—208,674 vaccinations were performed. Starting in with an average of 1,700 vaccinations a week in November, the number rose to 31,128 vaccinations in the week ending December 22d. The following week 27,263 vaccinations were performed, and since then the number has steadily fallen off, until now only 8,000 are vaccinated in one week. The number fell off from 13,976 vaccinations during the week ending February 9th to 8,531 during the week ending February 16th. At one time as high as 2,000 persons a day were vaccinated in the board of health building. Now hardly 25 vaccinations are performed in a single day.

Physician Poisoned by Mistake.—Dr. Edward A. Fessenden, Portland, Me., on February 28th swallowed two teaspoonfuls of a ninety-five-per-cent. solution of carbolic acid, by mistake, and died fifteen minutes after. Dr. Fessenden was born in Washington, Wis., fifty-five years ago, and graduated from Bellevue Medical College, New York. He served in the fifteenth Illinois infantry during the civil war and afterward practised at Clyde, Kans. He came to Portland eight years ago.

Arsenic in Coffee.—Commissioner Cosby, of the New York health department, has announced that an analysis of the coffee used some time ago in the household of Jaques Halle showed that there was sufficient arsenic in it to kill any one who had taken the coffee on an empty stomach. Mr. Halle and his family were made ill as a result of drinking the coffee served at their table on Valentine's day. An examination of the whole beans, both at the store from which the coffee was purchased and at the house, failed to reveal any arsenic, so that the only inference is that the poison was put in after the coffee had been brought to the house.

Lunacy Commissioners Bill Passed.—The senate on February 28th passed Senator Brackett's bill with regard to the qualifications of, and salaries to be paid to, the members of the State commission in lunacy. The final amendment, as suggested by Governor Odell, provides that the president of the commission must be a reputable physician, a graduate of an incorporated medical college, of at least ten years' experience in the actual practice of his profession, who has had five years' actual experience in the treatment of mental and nervous diseases, or who has had two years' experience in the care and treatment of the committed insane.

Plague in South Africa.—The *Medical Press*, February 16th, says: The sinister rumors to which we alluded last week, namely, that the plague had broken out in South Africa, has proved only too well founded. On the 10th inst. ten cases were reported from Cape Town. From the news to hand there can be little reasonable doubt that the disease is the true bubonic malady. Should the disease be conveyed to the front, the results may be of a terrible nature. The heavy mortality from enteric fever shows that the sanitary environment of the troops must be utterly defective in the elementary points of wholesomeness. If enteric fever can play such havoc, what may we expect from plague? Both maladies are "filth diseases," and the bad sanitation that fosters the one will extend an equal shelter to the other. The difficulties of the situation

indeed appear to be increased a hundredfold by the invasion of the Asiatic pest. Should the plague have already broken out among the British troops, it is to be hoped that the home authorities will lose no time in announcing the fact. The news that the disease had reached South Africa came to London first by way of the newspapers of Paris and Berlin. That information has now proved correct, and there is no particular reason, so far as can be seen, why the war office should not confirm or deny the further continental rumor that the pest has already killed a number of our soldiers. What is to be gained by silence? Has the war office taken any steps to furnish ample supplies of plague serum in case of such an outbreak at the front? Since this was written, news has come that there were over thirty cases of plague at Cape Town, but the rumor as to the disease having gained a foothold among the troops has not been confirmed.

Justice to Corning's Method of Spinal Anæsthesia.—Tuffier in his recent work on spinal anæsthesia,[1] in speaking of Corning's method, says: "Having done the operation more than two hundred and fifty times myself and taken cognizance of nearly a thousand cases reported to me by my pupils, I can recommend it." The large experience of the distinguished French surgeon is a very considerable item in balancing the pros and cons of the method in question. With this commendation is a frank acknowledgement of the value of our distinguished townsman's work, which very effectually settles the question of priority of discovery. In the beginning of the opening chapter, which is devoted to a review of the historical side of the subject, the accomplished author fully recognizes Dr. J. Leonard Corning, of New York, as the discoverer of spinal anæsthesia, and reviews his various contributions to the subject in an appreciative manner. Later, in a bibliographical index, comprising the literature of spinal anæsthesia which has recently appeared in France, America, Russia, Spain, Italy, and Germany, he places Corning's contributions at the head of the list. This is as it should be, and amply proves the true spirit of cosmopolitan justice when applied to meritorious scientific research.

Regarding the indications for spinal anæsthesia, he finds the procedure without danger in cases of cardiac disease and in those afflicted with arteriosclerosis. "Let each assign," he says, "to the method the particular field he chooses; for my part I consider it belongs in practice side by side with general and local anæsthesia."

The Law Says that Doctor Must Not Leave Patient.—Dr. P. H. Flood was ordered to pay $2,000 damages by the supreme court recently. Evidence showed that over a year ago he was called to attend Mrs. Margaret A. Lathrope. An operation was deemed necessary by him. Her screams interfered with his application of the necessary instruments. He finally said that if she "did not quit he would quit." And leave he did, although the patient was in agony. The husband followed the physician to the door, begging him not to go. He refused to come back, and it was over an hour before another doctor was obtained, the woman in the mean time suffering dreadfully. The other surgeon performed the operation, saving the mother's life at the expense of that of the child. Mr. and Mrs. Lathrope sued Dr. Flood and got a verdict for $2,000 in the superior court. Dr. Flood appealed the case to the supreme court, and yesterday the latter affirmed the lower court's action, saying, in part: "It is the undoubted law that a physician may elect whether or not he will give his services to a case, but having accepted his employment, and entered upon the discharge of his duties, he is bound to devote to the patient his best skill and attention, and to abandon the case only under one of two conditions. First, when the contract is terminated by the employer, which termination may be made immediately. Second, when it is terminated by the physician, which can be done only after due notice and an ample opportunity afforded to secure the presence of other medical attendance. . . . He can never be justified in abandoning it (case) as did this defendant, and the circumstances show a negligence in its character amounting wellnigh to brutality."—*San Francisco Examiner.*

The Abolition of the Canteen.—The doing away with the canteen has been the cause of grave dissatisfaction among the rank and file of the United States army. The supporters of the measure were doubtless swayed by the best of motives, but it is probable that the majority of them were more or less ignorant of the working of the system, and the community at large was led to believe that the canteens were the scenes of unbridled license and the great incentive to drink among the soldiers. It is impossible to make a man in any station of life refrain from drink by law, and the soldier is subject to this common failing; and if he cannot satisfy his appetite in one place, he certainly will in another. Better, then, that the canteen supplying wholesome liquor should be open to him than that he should be compelled to resort to outside drinking-shops where the quality of the liquor is dubious. *The Sun* stigmatizes the abolition of the canteen as, "instead of being a policy of enlightenment and wisdom, one both bigoted and unwise," and recommends that in the few days still remaining to Congress it should pass a bill to re-establish the canteen at the army posts.

Hearing on Osteopathy Bill before the New York Assembly Committee—The legislative committees of the State and county societies of New York had a hearing on Wednesday, February 26th, before the assembly committee, in opposition to the bill to legalize the practice of osteopathy. The impression the committees received after the hearing was that osteopathy was not likely to be licensed this year. The following gentlemen uttered their protests and did valiant service: Drs. Frank Van Vleet, Robert T. Morris, Charles N. Dowd, Floyd Crandall, representing the Medical Society of the County of New York; Drs. E. E. Harris and Joseph E. Messenger, representing the State Association; Dr. H. V. Barclay and Mr. Jacob

[1] "L'Analgésie Chirurgicale par Voie Rachidienne," par Le Dr. Tuffier, Professeur Agrégé à La Faculté de Médecine de Paris. Masson et Cie., Paris, 1901, pp. 44, vii.

Bolin, of the Society of Masseurs; Drs. H. D. Didama, Henry L. Elsner, Nathan Jacobson, and F. W. Sears, of Syracuse, Dr. Clark, of Buffalo, Dr. Eugene Beach, of Gloversville, Drs. Albert Vander Veer and Arthur G. Root, of Albany, besides the representatives of the homœopathic and eclectic branches of the profession. They were arrayed against the humorist Mark Twain, and Will Carleton, the playwright. The latter left after hearing some of the opposition. Mr. Twain, however, stuck it out, but failed to do more than amuse the audience, as it was expected he would.

German Quarantine against the Plague.—The announcement is made that the German government has established a plague quarantine against vessels from Cape Town.

A Physician Fined for Giving a Fake Certificate.—Dr. Moritz W. Dreyer, 60 McKibben Street, Brooklyn, has been fined $100 for filing a false certificate of death in the case of Renze Talpopsky. Death resulted from smallpox.

Increase of Plague in India.—Again this week, says *The Lancet* correspondent in India under date of January 24th, there is an increase in the plague mortality. For the whole of India 3,277 deaths are recorded, as against 2,839 during the previous seven days. The increase is chiefly in Bengal and the city of Bombay. For the Bengal presidency there were 2,181 deaths, of which Patna recorded 1,286 and Sarau 559. In Bombay city there were 370 deaths from plague, while the general mortality rose from 1,192 to 1,337.

Making Bad Use of His Time.—Because his physician told him he had only a week to live, Edward Menchaefer started out to spend the money he had saved during his lifetime. He brought up at the Stock Yards police station, Chicago, and paid a fine, after a hearing before Justice Fitzgerald. Menchaefer had been a teamster and a delivery clerk. He is about thirty years old. He had $150 saved. Of this amount he took out $30 to pay for his funeral and started to spend the rest in a riotous manner. What if the prognosis was wrong? What dreadful thing could be the matter with a teamster, thirty years old, to give him no chance for life?

County Medical Associations.—The following county medical associations, members of The New York State Medical Association, have been organized:

On January 22, 1901, The Westchester County Medical Association was organized. The following officers were elected: *President*, Dr. N. J. Sands, of Portchester; *Vice-President*, Dr. J. L. Porteous, of Yonkers; *Secretary and Treasurer*, Dr. D. T. McPhail, of Purdy's Station. Dr. E. F. Brush, Dr. H. Eugene Smith, Dr. P. J. Sands, and Dr. McPhail were elected members of the various committees required by the by-laws of the State Association.

On the 12th of February The Orange County Medical Association was organized, with the following officers: *President*, Dr. M. C. Conner, of Middletown; *Vice-President*, Dr. F. W. Dennis, of Unionville; *Secretary and Treasurer*, Dr. C. I. Redfield, of Middletown. Drs. C. Townsend, R. A. Taylor, W. E. Douglas, F. D. Myers, Joseph B. Hallett, William Evans, Charles A. Canfield, Edward Woodhull, Henry S. Swartwout, and E. A. Nugent were elected members of the various committees required by the by-laws of the State association.

The Sullivan County Medical Association was organized on February 19th with the following officers: *President*, Dr. C. S. Payne, Liberty, N. Y.; *First Vice-President*, Dr. Frank Howser, Centerville Station, N. Y.; *Second Vice-President*, Dr. S. W. Wells, Liberty, N. Y.; *Secretary*, Dr. J. L. C. Whitcomb, Liberty, N. Y.; *Treasurer*, Dr. C. W. Piper, Wurtsboro, N. Y.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for week ended March 2, 1901. Surgeon G. Pickrell detached from the Cavite naval station, and ordered to the Mare Island navy yard. Assistant Surgeon J. C. Thompson detached from the *Solace* and ordered home to wait orders. Surgeon A. R. Wentworth detached from the *Independence* and ordered to the *Solace*. Surgeon F. J. B. Corderio detached from the *New Orleans* and ordered home via the *Buffalo*. Surgeon C. F. Stokes detached from the *Buffalo* and ordered to the *New Orleans*. Medical Inspector F. Rogers detached from recruiting duty and ordered to the Asiatic station as fleet surgeon. Medical Inspector R. C. Persons detached from duty as fleet surgeon of the Asiatic station, and ordered home to wait orders. Surgeon W. H. Rush, retired, detached from the Pensacola navy yard and ordered home.

Charges against a Homœopathic Hospital.—Professor Francis Bacon, says the New York *Sun* of March 4th, lecturer on medical jurisprudence in Yale University, a well-known physician of New Haven, Conn., to-day made a scathing criticism of the methods and management of Grace Hospital of New Haven, an institution that is under the direction of homœopathists. He was discussing the measure in the Connecticut general assembly, to provide for a State hospital for the treatment of tuberculosis, and said that such a hospital should be for the benefit of patients, and not for the benefits of doctors. Dr. Bacon said that Grace Hospital receives an annual subsidy from the State, and at the same time is run in the interest of certain physicians, who beguile the patients there into paying them fees that are not authorized by law. He declared that Grace Hospital partakes largely of the character of a boarding-house maintained at public expense for the benefit of some doctors who use it to extract fees from helpless patients. Dr. Bacon then cited some cases of this nature which had come under his immediate notice, and concluded by stating that since the establishment of New Haven Hospital, nearly one hundred years ago, no fees for medical attendance or surgical operations have ever been received by any of the medical staff.

Clinical Buildings for Yale Medical Department.—By the generous gift of $100,000 from a friend of the Yale Medical School, whose name is withheld, this department of Yale will have, in less than a year,

one of the largest and most thoroughly equipped clinical buildings in the country. The plans have been completed by the architect, Mr. L. W. Robinson of New Haven. Work will be begun very soon, and by next February it is hoped to have everything complete in the building and its equipment. The demand for such a building, to utilize the dispensary cases for teaching purposes, has been for a long time felt as the first and greatest need of the Medical School. The scheme for building calls next for a pathological laboratory. This would require about the same amount of money as the clinical building. With this completed, the instruction for the last two years of the course would be practically all taken care of on the new grounds near the hospital. The equipment for the first two years will be quite complete for some time to come in the present quarters, with the exception of the department of anatomy, which should have a new building in the near future.

A Loss to Science.—The Pathological Institute at Berlin was no doubt known to the whole scientific world, for it contained the wonderful Virchow collection; but a fire broke out recently and destroyed the entire collection, among which were documents, etc., of universal interest.

The Hunterian Oration.—The Hunterian oration of the Hunterian Society was delivered by Mr. John Poland on February 13, 1901, at 8:30 P.M., in the London Institution. The subject was a retrospect of surgery during the past century. The annual dinner of the society has been postponed, says the *British Medical Journal*, to March 15, 1901.

Trouble at the Bath Home.—Dr. James T. Burdick, of Brooklyn, was on Saturday, February 23d, appointed head surgeon at the hospital of the State Soldiers' and Sailors' Home at Bath, by the trustees of that institution in annual session. The present head surgeon is Dr. Oran W. Smith. A misunderstanding has arisen with regard to the question as to whether Dr. Smith has resigned or not. He says that two months ago he handed in his resignation to Commander Davidson, but about two weeks ago withdrew it. The trustees declare that they regarded the resignation as accepted, and so the matter now stands.

Memorial to the Late Prof. Joseph Coats, of Glasgow.—A sum of £1,200 ($6,000) having been raised by the friends and admirers of Dr. Coats, late professor of pathology in the University of Glasgow, for the purpose of raising a memorial to him, the subscription committee has arranged with the University Court that the University of Glasgow shall found a scholarship, to be known as the "Joseph Coats Memorial Scholarship in Pathology," as a memorial of his distinguished services in pathological science, and in recognition of the ability and enthusiasm which he devoted to advance the teaching of the subject in Glasgow. The scholarship will be for the encouragement of original research in pathology, and will be tenable for one year. It will be of the value of the free income of the sum of £1,200 ($6,000) for the two preceding years, and will be awarded biennially.

Obituary Notes.—Dr. Charles Austin Ross, assistant surgeon, United States army, was killed in Northern Luzon, Philippine Islands, on Saturday, February 2d. A soldier had been shot and Dr. Ross started out into the field to dress his wound when he was shot from ambush. Dr. Ross was twenty-six years of age, and received his commission only last September. He had been in service but three months. He graduated with first honors from the Kentucky School of Medicine in Louisville, in the class of 1897. He served one year as resident physician of the Louisville City Hospital, where he exhibited unusual qualities as a surgeon. He began practice at Leopold, Ind., and had been there two years when he joined the army. He leaves a widow residing in Evansville, Ind.

Max von Pettenkofer, the founder of scientific hygiene and known as such all the world over, died in Munich by his own hand on February 10th. He is stated to have committed suicide while in a state of melancholia, due to a dread of losing his reason. He was eighty-three years of age, having been born at Lichtenhein, Bavaria, in 1818. He first turned his attention to hygiene in 1850, on account of the unhealthy state of Munich, in which city he was then settled. Enteric fever was prevalent there nearly the whole year, and the place was frequently visited by cholera of a particularly malignant type. He studied the disease closely and propounded the theory that this malady flourished when the subsoil water was low. This held the field until the bacteriological school, headed by Koch, arose. For some time war raged between Pettenkofer and his disciples, and Koch and his followers, but eventually a compromise was arrived at, the truth being recognized that the two theories were not incompatible. Pettenkofer gave practical proofs of his knowledge of hygiene by rendering Munich—at one time a most insalubrious city—a model of good sanitation and healthfulness. Pettenkofer will always be remembered as the leader in the development of modern hygiene, and one of the greatest benefactors to the human race.

Leslie Ogilvie, B.Sc., M.B. Edin., M.R.C.P., London, died at his residence in that city on February 2d, aged forty-nine years. Dr. Ogilvie was a very distinguished graduate of Edinburgh University, and a literary man of many parts. He was a remarkably successful practitioner, but of late years his chief interest has been in insurance work.

Dr. Richard J. Dunglison died at his home in Philadelphia March 4th. He was a son of Prof. Robley Dunglison and a grandson of Dr. John Leadam, a celebrated London physician. He was graduated from Jefferson Medical College in 1856. After devoting several years to practice he relinquished it for literary work. He was editor of "Dunglison's Medical Dictionary" and "History of Medicine." He was in the federal army service from 1862 to 1865, acting as assistant surgeon on duty in the hospitals in Philadelphia. He was assistant secretary of the International Medical Congress in 1876, and corresponding secretary of the Centennial Medical Commission, and at various times occupied important offices at medical congresses.

Progress of Medical Science.

New York Medical Journal, March 2, 1901.

Metrorrhagia due to Inflammatory Processes within the Pelvis.—By E. B. Craigin. Three factors must be considered in the etiology of metrorrhagia due to inflammatory conditions within the pelvis: First, the endometrium, where the sequence of changes is, chronic congestion followed by chronic inflammation of the endometrium, menorrhagia, and metrorrhagia. Second, the muscular wall of the uterus: here the etiological factors are tumors of the uterine wall and chronic interstitial inflammation of the uterine wall, in which there is an atrophy of the muscular tissue and an increase of connective tissue. Third, the blood-vessels of the uterus. In the same way that interference with the normal muscular contraction of the uterine wall favors an excess of blood in and from the uterus, so interference with the normal contraction of the arteries themselves favors the same result. Occasionally, especially in the later part of menstrual life, and often associated with the two conditions just discussed, viz., tumors of the uterine wall and chronic interstitial inflammation of it, one finds the vessels of the uterus in a condition of arteriosclerosis, with insufficient elasticity either to maintain the normal balance of uterine circulation or to check the flow beginning at a menstrual period. Here, again, although this inflammation of the arterial wall usually produces metrorrhagia through the medium of a chronic endometritis, occasionally cases are met with in which the endometritis is slight, or does not respond to the use of the curette, and in which the hemorrhage seems due to the lack of contractile power in the arterial wall.

The Electro-Chemical Action of the X-Rays in Tuberculosis.—By J. Rudis-Jicincky. The following experiments were performed: Tuberculous sputa were sealed up in fish bladders along with a suitable nutrient medium and then submitted to the rays. In general it was found that the action of the rays was destructive to the tubercle bacillus when in acid media. A series of experiments was then made on rabbits and guinea pigs, the animals being subsequently exposed to the rays. In forty per cent. of the animals thus treated, and killed after the lapse of two years, autopsy showed that actual cure, in the real sense of the word, of the tuberculous process had occurred when the acid condition was produced. Finally, the author treated twenty cases of pulmonary tuberculosis with the *x*-rays. Of these one patient died within the year, from tuberculosis of the bowel, another committed suicide, four were without improvement, while the remainder were doing comparatively well at the time of the report. The author does not conclude that the results were necessarily the consequence of exposure to the rays, for he utilized to the utmost good food, fresh air, and hygienic surroundings. He feels encouraged, however, to continue his researches along this line.

The Palliative Operative Treatment of Carcinoma of the Posterior Wall of the Stomach. — A. Vander Veer's conclusions are as follows: (1) In all cases of continued gastric disturbances that do not yield to medical treatment, a careful examination and experiment should be made as to the possibility of malignancy being present. (2) Whether a positive diagnosis of malignancy is made or not, the patient continuing to emaciate, and sufferiug more and more, an exploration should be done, and if there is no malignant growth a gastro-intestinal anastomosis should be made. (3) Malignant growths in the posterior wall of the stomach are certainly more difficult of diagnosis, and sometimes escape the notice of the most careful diagnostician. (4) When we have made an exploratory incision, and the growth is found to be in the posterior wall of the stomach, malignant in character, with no possibility of removal by resection or otherwise, although quite deep, yet we should not refuse our patient the benefit of a gastro-intestinal anastomosis. (5) In all of these cases the blood should be carefully examined, as part of the history of the patient, in order to learn of such conditions as may have a bearing upon the nature of the growth.

The Axis-Traction Forceps with Special Rotary Axis Traction in the Treatment of Posterior Positions of the Anatomical Head.—By S. Marx. The paper is a general advocacy of the Tarnier instrument, with a discussion of its special value in the clinical condition noted in the title, and a description of its mechanical action. The author says that in many occipito-posterior cases he has, by the use of the axis-traction instrument, succeeded in rotating the head anteriorly by simply allowing the head, while traction is being made, to be influenced by the factors supplied by nature (the resistance offered by the perineal structures and furthered by the turning-points afforded by the ischial spines, especially when they are prominent) to provoke such rotation. The great advantage of the axis-traction forceps over the ordinary variety, in the condition named, is the greatly lessened danger of rupture of the maternal parts.

Hemorrhage from a Circumtonsillar Abscess.—By W. F. Chappell. The patient was a man aged twenty-seven years, with an abscess pointing in the middle of the left posterior pillar of the soft palate. Incision evacuated about half an ounce of foul pus. Four days later he had a hemorrhage of about six ounces in amount. The hemorrhage recurred several times and the original abscess cavity filled with blood clots. An incision was made through the anterior surface of the soft palate into the cavity, the clots were turned out, and the cavity was packed. These measures finally controlled the bleeding. The urine had meantime been examined and showed considerable albumin, epithelial and pus cells, and granular casts with adherent pus corpuscles. Chappell has found records of ten similar cases with two recoveries.

The Pathology of Intra-Uterine Death.—By Neil MacPhatter.

Cancer of the Uterus.—By A. F. Currier.

Medical News, March 2, 1901.

Thymotal; a New Remedy for Ankylostomiasis.—J. E. Pool prefers this new remedy thymotal to thymol, for the following reasons: (1) Because it is without odor, and can therefore be taken by children who cannot swallow pills. At the same time the danger of being suffocated by thymol electuarium, which occasionally happens in infants, is avoided; (2) because it is not dissolved in the stomach as is thymol, and is not vomited as is often the case with the latter; (3) because thymotal does not cause giddiness, as thymol does very shortly after it is taken; (4) because the danger of thymol poisoning is reduced, especially in those children whose bodies are weakened by ankylostoma; (5) because the carbonate of thymol is broken up in the body by the influence of the bile and the mucus of the intestines, and thymol is formed exactly at the places where the ankylostoma are found in the body, *i.e.*, the duodenum and the adjacent parts of the intestines; (6) because it cures more rapidly than does thymol (as far as can be judged from the treatment of this small number of patients —seven). The writer proceeds to give the following directions for the administration of this drug: For adults, 2.0 gm. (gr. xxx.); for children, 1.0 gm. (gr. xv.), and for babes, 0.5 gm. (gr. viiss.) three or four times daily. This treatment must be continued for four days, and a purgative must be taken on the fifth day, after which the whole treatment must be repeated until no more eggs of ankylostoma are found in the stools.

The Treatment of Delirium Tremens by the Intravenous Infusion of Saline Solution.—James P. Warbasse reports a case of this kind, and states that the infusion under such circumstances increases the amount of the circulating medium in which the toxic materials are dissolved, thereby diluting the poison and bathing the nerve centres with a more attenuated solution of the same. The amount of circulating fluid is increased above the normal, so that the excretion of fluids through all the fluid-excreting channels is increased, thereby carrying off in solution much of the contained toxins. The action of the heart is improved by the filling of the relaxed vessels. These suffice to restore the physiological equilibrium and turn the balance in favor of recovery. Thus we may add indefinitely to the uses of this most valuable therapeutic measure.

The Use of the Aqueous Extract of the Suprarenal Gland in Persistent Epistaxis.—Lewis S. Somers states that theoretical studies of the suprarenal gland would indicate that it possessed the characteristics of a superior local hæmostatic and vasomotor constrictor, and on practical observation this is found to be true. It has no effect on the blood itself—does not form a clot—but, within a few seconds after application to the mucous membrane, blanching of the surface ensues from the wonderful constricting properties of the drug. It has proved invaluable in the treatment of persistent epistaxis. When congestion or erosion of the mucous membrane exists, a general nutritive tone is given to the tissues that no other local remedy seems to possess. It has the properties of a pure muscle tonic.

On the Desirability of Combined Operations in Pelvic and Abdominal Surgery.—W. P. Manton concludes his article by saying that in his opinion, in every instance, whatever is necessary should be done, whether the conditions lie within the pelvis, the abdomen, or in both; and the limit of execution should be gauged only by the general condition of the patient, her behavior under the anæsthetic, and the inherent dangers of the operations to be performed. These, together with experience, skilful operating, strict asepticism, and watchful care of the patient, are the *sine qua non* of success.

The Journal of the Amer. Med. Ass'n, March 2, 1901.

Bony Defects and Fistulæ in the External Meatus.—H. Gradle states that the occurence of artificial communicating passages between the meatus and attic of the middle ear is not a rare lesion. The defect is usually a fissure of variable size in the external wall of the attic, opening through the upper wall of the meatus above Shrapnell's membrane. It is not always possible to distinguish between a fistula and a complete gap. Small defects are difficult to recognize by sight and may be found only by the use of the probe. Most of the writer's cases were seen on account of the discharge. Some patients had no secretion at the time of examination, but asked help for their hearing. The patients were all adults who dated the ear trouble back to childhood. Relapse must be expected in some of these cases, but they are as easily checked as is the previous disease. The treatment of chronic otitic suppuration is not altered by the existence of bony defects, perhaps even facilitated. The all-important condition is the complete removal of all pent-up discharge, as well as cholesteatomatous masses. An infallible guide for controlling the efficacy of the treatment is the odor of the discharge. A fetid smell shows pus retention. As long as this exists no complete cure is possible, while the removal of the odor is proof positive that the conditions are now favorable for cicatrization.

Treatment of Chronic Otorrhœa.—Frank Allport emphasizes the existence of the diversity of opinions concerning the treatment of chronic otorrhœa, and he believes that much misunderstanding could be averted if conditions rather than a name were considered. A chronically discharging ear does not always indicate the same pathological conditions. A simple exudative mucous-membrane inflammation may exist, with imperfect drainage, which may be healed by an enlarged opening and simple treatment; or exuberant granulations may be present, which are removable and curable; or ossicular or mural caries may occur, relievable by acids, drainage, treatment, etc., or by an ossiculectomy and curettage; or the disease may have extended farther into the antrum; or the mastoid antrum and cells may be involved, and possibly the sinuses and intracranial contents, calling for prompt and large operative procedures. It is best to examine each case independently as to its pathological condition, symptoms, duration, and character of its discharge, etc., and advise a plan of action harmonious with such unprejudiced examinations and observations. The dividing pathological line seems to be the extension of the disease to the antrum.

Address before the New York State Assembly Committee on Public Health.—Robert T. Morris considers the subjects of osteopathy and "Christian science." The writer believes that the osteopaths must of necessity benefit many cases which are adapted to their methods of treatment, and our objection to licensing them is that they are wishing to assume too great responsibilities on a small margin of medical education. All we ask of them is that they pass the examination in the rudiments of medical knowledge, which our State requires of physicians, and after that they may practise what they wish. As to "Christian scientists," the proportion of good which they do, as compared to the injury resulting from neglect of cases for which they assume responsibility, would not appeal to honorable legislators as justifying their protection under our medical practice laws.

An Original Chart of the Neuronic Architecture of the Visual Apparatus.—Louis Stricker, after reading the recent work of St. Bernheim, of Vienna, on "The Nuclear Origin of the Ocular Nerves and their Connection with the Cortex of the Brain," and finding no comprehensive diagram from which a general conception of this intricate mechanism could be gleaned, has prepared a chart which represents an entire cross section of the brain, made on a level with the optic thalami: the temporal and frontal lobes have been cut away, as has also the cerebellum, thus exposing the pons and medulla. The chart is given with explanations.

A Protest against the Use of Proprietary Remedies.—Daniel R. Brower earnestly protests against the present tendency to use so freely the proprietary remedies. He believes that we have in our armamentarium enough well-tried remedies that have been subjected to unbiassed and careful physiological tests, and have passed through the ordeal of scientific clinical applications to enable us to fulfil the mission intrusted to us.

Combined Sclerosis of Lichtheim-Putnam-Dana Type Accompanying Pernicious Anæmia.—By M. A. Brown, F. W. Langdon, and D. I. Wolfstein.

Aphasia with Letter-Blindness, without Word-Blindness, with Right Hemiplegia and Pulmonary Tuberculosis.—By Guy Hinsdale.

Cultivation of the Æstivo-Autumnal Malarial Parasite in the Mosquito—Anopheles Quadrimaculatus.—By Albert Woldert.

Anastomosis of the Ureters with the Intestine: a Historical and Experimental Research.—By Reuben Peterson.

The Results of the Surgical Treatment of Inflammation of the Mastoid Process.—By Edward Bradford Dench.

Irrigation of the Colon as a Therapeutic Measure.—By George J. Lochboehler.

Croupous Pneumonia.—By J. M. Allen.

The Boston Medical and Surg. Jour., February 28, 1901.

The Use and Abuse of Spectacles.—Hasket Derby protests against the use of glasses when they are not absolutely necessary. If hypermetropia be moderate, it is a mistake to use glasses for anything but close work, for the patient is reduced to a dependence upon them which might be avoided. In myopia glasses are probably worn too little, but great care must be exercised in treatment, and no glass should be ordered until a thorough investigation of the history of the patient, the family tendencies, the acuteness of vision, and the condition of the interior of the eye has been made. As to astigmatism, so much relief has been given by glasses that the tendency is to prescribe them when they are not strictly needed. The author believes that they can be dispensed with in cases in which vision, either with or without a spherical glass, is found equal in unity. As to muscular weakness, it is often cured by an improved general condition, without the use of prisms.

Clinical Meeting of the Medical Board of the Massachusetts General Hospital.—"Case of Brain Tumor with Astereognosis," by Dr. Walton; "Operation for the Removal of a Foreign Body Impacted in the Œsophagus for More than two Weeks," "Backward Dislocation of the Ulna; Fracture of the External Condyle of the Humerus; Fracture of the Radius and Ulna near the Wrist Joint," "Retention of Urine from Obstruction by the Third Lobe of the Prostate Gland," by H. H. A. Beach; "A Series of Cases Illustrative of the Clinical Importance of Bacteriological Examinations," "Idiopathic Dilatation of the Colon; Chronic Rheumatic Arthritis; Chronic Mitral Endocarditis; Hemiplegia; Embedded Needle," by M. R. H. Fitz; "Case of Gunshot Wound," by C. A. Porter.

Two Cases of Ligature of the Internal Jugular Vein for Infective Thrombosis of the Sigmoid Sinus Due to Purulent Otitis Media; One Recovery and One Death.—Frederick L. Jack concludes that in acute cases, before ligating the vein, we should remove the purulent material in the sinus until a healthy clot is reached. After this operation, if rigors and elevation of temperature recur immediately, the jugular vein should be ligated and the entire thrombus removed above and below, until a free flow of blood takes place. If at the original operation no healthy clot is found, there should be immediate ligation. In chronic cases no time should be lost in ligating the vein and completely removing the thrombus.

Avulsion of the Finger, with a Case in which this Accident Occurred to an Infant Twenty Months Old.—George H. Monks reports a case in which the little finger was torn off, carrying a long portion of the flexor tendon with it. In cases of this kind no attempt should be made to replace the avulsed portion of the finger, as has sometimes been done with severed digits. An injury of this nature has damaged the part beyond possibility of repair. In order to get flaps it will always be necessary to dissect out a portion of the bone in the stump. The operation is simple, and the results are almost always good as to healing.

The Lancet, February 23, 1901.

Persistent Metrorrhagia.—By J. Inglis Parsons. In cases without apparent cause, the indication is to use the curette. If the endometrium which is scraped off is found to be

thickened, the curetting does good and the metrorrhagia usually stops, at any rate for some months. On the other hand, in a certain number of cases very little thickening of the endometrium is found, and then the metrorrhagia will often persist, and perhaps be worse after the curetting than before. In such cases he has been able to stop the hemorrhage permanently by the use of the constant current. The applications are made by means of a platinum electrode with a movable insulating sheath. This is passed up to the fundus of the uterus, while the insulating sheath is adjusted so as to reach just beyond the internal os. As the bleeding comes from the body of the uterus, it is absolutely essential to success to see that the current comes off in the body of the uterus and not in the cervix. A clay pad is placed on the wall of the abdomen just above the pubes, and connected to the negative pole, while the intra-uterine electrode is connected to the positive pole. At the first application only a mild current should be used, not more than fifty milliamperes, but subsequently it can be slowly raised until the galvanometer indicates from seventy-five to one hundred milliamperes. This is kept on for ten or fifteen minutes. The patient need not lay up during the treatment, and, except in extreme cases, can come to her medical man's house for the treatment. The applications are made twice a week. An antiseptic vaginal douche should be used every day, morning and evening. The electrode must be absolutely clean and should be placed in an antiseptic solution, like any other instrument, before being used for operation.

The Diagnosis and Treatment of Abscess in Connection with the Vermiform Appendix.—By R. Morrison. The author calls attention to the fact that in appendicular inflammations the absence of the ordinary signs of pus formation is no reliable guide in excluding its existence. There are often no rigor, no pus temperature, no redness or œdema in the right iliac fossa, and no evidence of deep fluctuation, yet an abscess may be present. The main lines of argument in the paper are indicated by the following propositions: A dangerous abscess may be present, without any of the ordinary signs or symptoms of pus formation. The diagnosis must be based on the history of the case, that is, of an acute attack of appendicitis and the presence of a definite tender lump. The position of the appendix and the relations of the abscess may be foretold by a careful study of the tumor. The diagnosis of pelvic cases in women is attended by special difficulties. In men and women bimanual examination may clear up an otherwise doubtful case. Spontaneous relief and possible cure may follow the discharge of pus into the adjacent bowel. An abscess, though of appendicular origin, may be remote from the appendix and may be residual. Many of such pus collections are due to the localization of a general peritoneal infection which has been recovered from. Early operation is the proper treatment, and with few exceptions the vermiform appendix should be removed at the same time as the abscess is drained (pelvic cases form the chief exception to this rule). The abdominal opening should be large enough to permit of perfect inspection of all manipulation, and the abscess should be drained from behind.

Quiet Effusion into the Knee Joints Occurring in Women and Young Girls.—Clinical lecture by W. H. Bennett. The author's attention was called to this condition by his seeing a number of cases of painless and unnoticed effusion into the knee joints of girls from twelve to fourteen years of age. In all there was delayed onset of menstruation. In some instances the children seemed to tire easily and were prone to fall down or "double up" without obvious cause. The joints were never tense except in case of superadded injury. When the patients stood up the fluid seemed to gravitate to the lower part of the cavity, and the synovial membrane hung over like a pouch at its lower anterior aspect. There was no tension, heat, or pain. The patients were usually anæmic. A somewhat similar series of cases was observed in older women, but in all there was a menstrual disturbance. The primary treatment must be directed to the correction of the faulty functions. Moderate exercise should be ordered, with massage for the knees. Splints should be most carefully avoided, and the patient encouraged to lead an outdoor life and be prevented from degenerating into the class of chronic invalids. The author advises the routine examination (when this painless effusion exists) into the condition of the monthly function; for the rectification of the latter when abnormalities exist will often lead to a disappearance of the joint trouble.

The Surgery of Pregnancy and Labor Complicated with Tumors.—Third lecture by J. Bland-Sutton. The special complications here considered are cancer of the uterine neck, pelvic growths, misplaced viscera, sequestered and quick extra-uterine fœtuses. In reference to the last-named class the author says that in dealing with the question of concurrent intra- and extra-uterine gestation we have three classes of cases to consider: (1) Cases in which uterine pregnancy supervenes on a quiescent (sequestered) extra-uterine fœtus, and goes to full term. In these circumstances it may end happily and be successfully repeated. (2) An extra-uterine and a uterine pregnancy begin simultaneously, but the complication is recognized in the early months and terminated by surgical intervention. (3) Uterine and extra-uterine pregnancy running concurrently to term. All the recorded examples of this extremely rare combination have, with one exception, ended in disaster to the mother.

Points in the Classification and Diagnosis of Some Joint Affections.—By G. A. Bannatyne. Arthritic troubles may arise from (1) bacteria acting themselves on joint structures, (2) from bacterial poisons, as in pulmonary osteoarthropathy, (3) from toxic poisons of as yet undetermined character, like gout, (4) from nerve degenerations, and (5) from senile degenerations. Under the head of toxic arthropathies are included rheumatism, rheumatoid arthritis, scarlatinal arthritis, and, probably, malarial arthritis. The author discusses the various characteristics of cases, following out the above clinical division.

Abstract of an Interim Report on Yellow Fever by the Yellow-Fever Commission of the Liverpool School of Tropical Medicine.—By H. E. Durham and W. Myers.

On Protective Inoculation and Serum Therapy.—By J. L. Bunch. A historical review of the development of this theory.

British Medical Journal, February 23, 1901.

Remarks on the Conclusions of the Report of the Anæsthetics Committee of the British Medical Association.—George Eastes states that although (excluding nitrous oxide) ether may be accepted as the safest routine agent, certain circumstances determined by the state of the patient, the nature of the operation, etc., may render the use of some other anæsthetic or combination of anæsthetics both safer and easier. As to the best methods of restoration, the subcommittee are unable from the material at their disposal to draw any conclusion upon this point. Anæsthetics are more commonly associated with complications and dangers in males than in females. Excluding infancy, and taking anæsthetics collectively, the complications and dangers of anæsthesia increase *pari passu* with advancing age. Anæsthetics are notably more dangerous in proportion as the gravity of the patient's state increases. The tendency for complications, dangerous and otherwise, to occur increases *pari passu* with the gravity of the operation. Danger to life is especially likely to be incurred in early periods of the administration of anæsthetics, while the tendency to less grave complications increases directly with the duration of anæsthesia. While the respiratory complications of anæsthesia as a whole are of equal frequency under the ether and chloroform groups respectively, yet those that occur under ether are mostly of a trifling and transitory nature, while those that occur under chloroform are more grave and persistent. The A. C. E. mixture in most of the statistical tables holds an intermediate position between chloroform and ether. From all the study that has been given to this whole subject, the most important factor in the safe administration of anæsthetics appears to be the experience which has been acquired by the administrator.

A Criticism of the Report of the Anæsthetics Committee of the British Medical Association.—Augustus D. Waller declares that clinical inquiry, as exemplified in the ninth and final report of the anæsthetics committee of the British Medical Association, has said its say after ten years of careful deliberation, and it is evident that further clinical inquiry on these lines can serve no useful purpose. As to the statement that the most important factor in the safe administration of anæsthetics is the experience of the administrator, and that often it is essential that a man of large experience should give the anæsthetic, the writer states that certain definite steps should be taken to the acquirement of knowledge in this branch, which will have an influence on the death rate by chloroform: (1) An experimental examination of the statement that, by proper application of a volumetric method, anæsthesia can be certainly effected of any required degree. (2) An experimental comparison of the relative power of various anæsthetics. (3) The determination of the best method of quantitative estimation of anæsthetics in the various fluids and tissues of the body. (4) A careful redetermination of the statements made by Snow, Gréhaut, Paul Bert, and Dubois, with reference to the percentage of chloroform required for various degrees of anæsthesia, and the percentage of chloroform in the fluids and tissues of animals variously anæsthetized.

Liverpool School of Tropical Medicine: Yellow-Fever Expedition.—Herbert E. Durham and Walter Myers state that sufficient search reveals the presence of a fine small bacillus in the organs in all fatal cases of yellow fever. It

is probable that this same bacillus has been met with but not recognized by others, for it takes up stains with difficulty and it is hard to establish its growth on artificial media. The most successful staining method is by carbolic fuchsin solution, diluted with five-per-cent. phenol solution, immersion for several hours, followed by differentiation in weak acetic acid. The writers believe that yellow fever is not due to parasites of the nature of protozoa. They also believe that the endeavor to prove a man-to-man transference of yellow fever by means of a particular kind of gnat is hardly intelligible in a bacillary disease. They hold the opinion that the evidence in favor of the etiological importance of the fine small bacillus is stronger than any that has yet been adduced for any other pretended "yellow-fever germ." At the same time there is a much further work to be done before its final establishment can be claimed. The acquisition of a new intestinal bacterium would explain the immunity of the "acclimatized."

A Note on the Phenyl-Hydrazin Test for Sugar.—G. Leslie Eastes gives the following directions: Take of the filtered urine about 60 c.c. in a beaker of 100 c.c. capacity. Add 1 gm. of sodic acetate and rather less of the phenyl-hydrazin hydrochlorate. Stir with a glass rod, which remains in the beaker throughout the entire operation. The beaker is then placed on a water bath and the urine gradnally evaporated down to 10 to 15 c.c. During this process the beaker should be ocasionally removed, and any sediment collected on the sides of the vessel scraped off with the glass rod into the flnid. When reduced to the bulk above indicated, the flame should be removed and, the beaker remaining on the bath, the whole should be allowed to cool. This will take two hours or longer. When quite cold, all sediment should be stirred up, and with a pipette some placed on a glass slide for microscopical examination. Osazone crystals will have formed if there is one part per thousand or more of sugar in the urine. If no crystals are found, it may be safely concluded that sugar (that is, glucose) is absent.

A Note on the Phenyl-Hydrazin Test for Sugar.—Walker Hall, from his own experiments on this subject, concludes that it appears that 0.5 gm. (gr. vii. to viii.) of phenyl-hydrazin, 1.5 gm. (gr. xxiii.) of sodium acetate, and 5 c.c. (℥ ii.) of urine give the most rapid and satisfactory results with glucose, but that 10 c.c. should be taken if the solution contains maltose or lactose. These quantities are approximately Williamson's directions, and answer with 0.1 to 5 per cent. solutions; if a higher percentage is present, the solution of urine should be diluted. Crystals are almost without exception obtained at the first trial.

Observations on Malaria and Mosquitos in Queensland and British New Guinea.—Sir Francis P. Winter thinks that researches in a country in which malarial fever is common, but in which mosquitos are unknown, or at least are very uncommon, would be more likely to lead to conclusive proofs, one way or the other, than researches in a country that is a congenial home of the mosquito and of malaria. In Clermont, Queensland, the writer never felt or saw a mosquito in two and a half years, but malarial fever was common. In New Guinea, although he was frequently bitten by mosquitos, he did not develop malarial fever until after he had been a year and eight months in the country.

Malaria and Elephantiasis in Relation to Mosquitos in the Marquesas Islands in the Pacific Archipelago.—D. H. O'Neill, in a letter to *The Lancet*, quotes from R. L. Stevenson as follows: "In Atuona, a village planted in a shore-side marsh, the houses standing everywhere intermingled with the pools of a taro garden, we find every condition of tropical danger and discomfort, and yet there are not even mosquitos, nor even the hateful day fly of Wuka-Niva, and fever and its concomitant, the island fe'efe'e, are unknown." The absence of fever and elephantiasis from a locality which is also free from mosquitos, is a most interesting and suggestive observation.

Mosquitos and Malarial Parasites in Hong Kong.—John C. Thomas and J. M. Young submit statistics that fully bear out the theory of the relationship of cause and effect between mosquitos and malaria. They hold that all temporary measures for the improvement of the health of the station at Jai Po should be superseded with as little delay as possible by a definite scheme for the complete eradication of the breeding-places of the Anopheles over the wide area surrounding the police station.

A Slide Tray for Ward Use.—J. C. Thompson describes and illustrates a convenient slide tray devised by Dr. Chung, resident surgeon in the Tung-Wah Hospital, Hong Kong.

Dublin Journal of Medical Sciences, February, 1901.

Removal of Epithelioma of Cervix Uteri during Pregnancy, and Vaginal Hysterectomy after Delivery.—By R. J. Kinkead. The patient was a woman of twenty-eight years, multipara, admitted to the hospital in the eighth month of pregnancy. Bleeding had commenced from the uterus some two months previously. The cancerous growth was found to be small, though hemorrhage had been profuse. It ceased immediately on the removal of the growth. The latter was friable and broke down under the grip of the forceps employed to grasp it. It was removed with the finger and curette, the stump treated with perchloride of iron, and the vagina packed. The patient was discharged from the hospital and was delivered about six weeks later. She was then readmitted, the mass (which had regrown) removed, and a vaginal hysterectomy done. Secondary hemorrhage resulted, the bleeding area being located in the rectovaginal septum and right broad ligament. There was a general oozing, rather than bleeding from any particular vessel. The patient finally made a complete recovery.

Notes on Plague at the General Hospital, Belgium, 1899.—By R. H. W. Jackson.

Surgery as a Science and an Art.—By C. Y. Pearson.

Archivio per le Scienze Mediche, vol. xxiv., No. 4.

Two Cases of Syringomyelia.—Antonio Cesaris-Demel describes two cases, one of which belonged to the "Morvan" type, the other being a case of syringomyelia with lesion of the pituitary gland without acromegaly. The trophoneurotic lesions of the bones and articulations had no specific character, but were such as are found in other physiological (senility) or pathological (osteomalacia, etc.) processes. It is to be noted that the passive symptoms, such as lacunar atrophy, decalcification, fibrous and cartilaginous metaplasia predominated. Active processes, such as osteophytosis, the formation of callus in fractnres, etc., are but incompletely developed. Adenoma of the pituitary gland may be regarded as concomitant with the production of the medullary gliomatosis, and pathologically equivalent. As to the non-production of the acromegaly, it may be explained by supposing that a part of the adenomatons gland retained its functioning powers.

Removal of the Semicircular Canals.—Umberto Deganello finds that the removal of one or both canals always produces in pigeons changes in the cells of the nucleus of the abducens of both sides. In some cases there are also produced lesions of Purkinje's cells in the cerebellum. Some of the vestibular protoneurons which are connected with the semicircular canals terminate in the nucleus of the abducens. It is probable that all the rest of the vestibular protoneurons which are connected with the semicircular canals go directly to the cortex of the cerebellum. There is an intimate anatomical connection between the semicircular canals and the cerebellum on the one hand, and between them and the abducens on the other. If there is a lesion of a sensory neuron, symptoms of the lesion may be shown in the motor neuron which is related to it by contiguity.

The Important Influence of the Lime Salts in the Repair of Bones.—Angelo Valan has had good results from the injection of lime salts in experimental cases of loss of bone substance. Injected in powdered form they are absorbed too rapidly, and should therefore be held together by some substance which, while it allows of infiltration into the osteogenetic tissues, will retard the absorption of the calcareous particles, keeping them in reserve, as it were, for the later processes of repair. Calcined bone is the best substance for this purpose. The author submits a table of statistics relating to forty experiments upon animals.

The Transplantation of Interepiphyseal Cartilage.—By Alessandro Zoppi.

The Pathology of the Suprarenal Capsules.—By Pio Foà.

Revue de Chirurgie, February 10, 1901.

Osteomalacia.—G. Gayet and L. M. Bonnet conclude from their researches that osteomalacia, which consists in a deficiency of lime salts in the bones, may be localized

or general. The local form follows traumatism, infectious bone diseases, and some nervous troubles. In both local and generalized forms the anatomical lesions are identical. These lesions are not always the same, but present variations which have apparently no connection with the etiology, the clinical variety, nor the amount of generalization of the disease. Age, sex, climate, etc., have some predisposing influence; the determining causes are unknown, but it is probable that disorders of the nervous system play the chief rôle. The good effects of castration are perhaps to be explained by the fact that the ovarian secretion causes an active elimination of the phosphates.

"Peritonization" in Laparotomy.—E. Quénu and Judet claim that by their method of peritoneal autoplasty, which leaves the intestines as in health, covered by a smooth endothelial surface, the rate of mortality is lowered, patients suffer less from colicky pains, and abdominal drainage can be abolished in from two to four days. As to the remote effects, patients more rarely suffer from digestive troubles and abdominal pains. In the past five years the authors have had but one case of post-operative intestinal occlusion, due to intestinal paralysis after abdominal hysterectomy for fibroma. A second operation brought about complete recovery in this case.

Surgical Treatment of Diffuse Suppurative Peritonitis.—Edouard Loison advocates laparotomy in the peritonitis resulting from perforation of the small intestines in typhoid fever. The diagnosis of the condition is difficult but by no means impossible, and as soon as it is established, the operation should be decided upon. The author describes the various steps of the operation. He prefers a median incision. The perforation having been found, a suture is made in a transverse direction as a rule, although there are certain cases in which a longitudinal incision is better. Dressing and drainage are described in full.

Experimental Study of Fractures of the Upper Jaw.—By R. Le Fort. A continued article.

Ligature of the Abdominal Aorta.—By P. Tillaux and P. Riche. A continued article.

Chopart's Amputation.—By A. Lapointe. A continued article.

Archives Générales de Médecine, February, 1901.

Experimental Calomel Poisoning.—P. Jousset and Lefas injected calomel into three rabbits. The lesions caused in the liver were congestion, angio- and periangio-cholitis, and granular atrophy of the hepatic cells, with evidence of nuclear chromatolysis. These alterations are very similar to those found in the case of many infectious diseases, and would seem to mark the onset of biliary cirrhosis. The lesions in the kidneys were those of glomerulo-nephritis, and resembled those caused by infections, cantharidin, and possibly ricinus. In the lungs there were two varieties of lesions, the one of hypostatic broncho-pneumonia of the middle and lower lobes, the other of epithelial pneumonia.

Subacute Adenitis of the Groin.—G. Marion and C. Gandy describe an affection which is characterized by a slow development, marked functional symptoms, and a tendency to the formation of multiple and successive abscesses. All the cases studied by the authors were found to be tuberculous, the tubercle bacillus alone being responsible for the suppuration. No other micro-organisms were found, and inoculations of the pus caused manifestations of an attenuated form of tuberculosis in guinea-pigs. The proper treatment is extirpation if the surrounding tissues have not been invaded; otherwise, curettage.

Primary Juxta-Hepatic Cancer of the Bile Ducts.—P. Lecène and P. Paquiez report two cases of this rare affection. The cancer is situated in the hilum of the liver, surrounding the hepatic canal, or the origin of the ductus choledochus. It is always circumscribed, and the symptoms caused are the mechanical ones of stenosis of the larger bile ducts.

Jour. de Médecine et de Chir. Pratiques, Feb. 10, 1901.

The Administration of Arsenic.—M. Danlos is convinced that the best way of giving arsenious acid in long-continued treatment is by means of the Asiatic pill. The injection of arsenious acid hypodermically is likely to cause abscesses and usually occasions severe pain. The author has tried giving the medicament in a solution of glycerin, but without good result. Arseniate of sodium can be substituted for arsenious acid with advantage, being less toxic and better tolerated hypodermically. As a rule he prescribes the injection of a cubic centimetre (3 to 5 cgm. of sodium arseniate) every two days; no pain attends the process and no unpleasant results follow. In the destruction of cancroids, however, arsenious acid is the better form to use, and the author does so by moistening the following powder with water and laying it on the scraped surface: Arsenious acid 1 gm., cocaine hydrochlorate 1 gm., orthoform 10 gm. The cocaine gives immediate anæsthesia and the orthoform prevents later pains.

The Preventive Treatment of Hepatic Colic.—M. Chauffard recommends the administration of the salicylate of sodium in daily doses of 1 to 1.5 gm., given intermittently. That is to say, it can be taken for three weeks of a month, then fifteen days, and then ten days monthly, for as long as perhaps two years. Carlsbad salts can be added to the treatment occasionally, for patients who are inclined to be constipated. Harlem oil may be given in ten- to twenty-drop doses every week. This form of treatment has been found by Chauffard to be very efficacious in diminishing and even in suppressing the painful crises.

French Journals.

Treatment of Appendicitis.—H. Verneuil, in summing up the indications for operation in appendicitis as accepted by the majority of surgeons, states that: If the symptoms are from the very beginning severe (vomiting—bilious or fecal—constipation, pain in the iliac fossa and at McBurney's point, marked tympanites, scanty urine, dyspnœa, very high temperature—or low temperature—rapid pulse, anxious countenance), in a word, if there are present signs of generalized purulent peritonitis or of diffuse septic peritonitis, operation is necessary; a median cœliotomy should be performed, the appendix removed, and the wound drained. If the symptoms are such in the beginning that an acute appendicitis with circumscribed peritonitis is determined (sharp pain at McBurney's point, vomiting, constipation, a moderate fever, but full and regular pulse in accordance with the temperature, moderate meteorism, the general appearance good); if some little time has elapsed since the beginning, and there is found in the right iliac fossa a thickening, then medical treatment should be instituted (ice to the abdomen, opium, absolute quiet in the dorsal position, and iced Vichy in small quantities as a drink); the patient should be watched carefully, all things being in readiness for necessary intervention. After repeated attacks of appendicular colic, or of acute appendicitis without peritoneal reaction, after a crisis of acute appendicitis with circumscribed peritonitis, and in every case after a second crisis, the appendix should be removed. —*Journal de Chirurgie et Annales de la Société Belge de Chirurgie*, January-February, 1901.

Varices, Hemorrhoids, Varicoceles, Hydroceles, Serous Effusions Recently Treated with Guaiacol.—Allahverdiantz gives an interesting account of cases which he has treated by this new method. He reports seven instances of cure in cases of varices; three cures of varicoceles; five cures in cases of hemorrhoids. He describes the treatment as follows: The varicose member, or part, is bandaged with a solution of guaiacol, more or less concentrated, according to the tolerance of the part affected, and, in order to avoid contact with the air, the bandaged part is covered with rubber tissue, and the whole bandage is covered by a layer of wadding. The bandage is renewed morning and evening. The patient is kept quiet during the time of treatment, which varies generally from ten to twenty days. The only statement possible to make at present is that these affections so treated have disappeared without surgical intervention. Whether they will return, time alone can tell. After his success in the treatment of hydroceles, the writer tried the same treatment on pleuritic effusions, and in each case there was an immediate diminution, and, at the end of several days, a disappearance of the effusion, without recourse to puncture. Œdema yields also to the same treatment. The writer believes from his experience that guaiacol is one of our most valuable therapeutic agents.—*Bulletin Général de Thérapeutique*, February 15, 1901.

Two Cases Demonstrating the Presence of the Gonococcus in the Blood.—Léon Bertrand reports these cases and states that in all forms of acute rheumatism, whether localized or generalized, the organism is probably a prey to an acid dyscrasia: it is undoubtedly this which causes the acid reaction of the perspiration of these patients. In diabetes, which prepares a soil favorable for pus formation, the alkalinity of the blood is always diminished, and the presence of uric acid in the blood has often been determined. The most severe pneumonias, and those with complications—precisely as blennorrhagia—as arthritis, endocarditis, and peritonitis, are the pneumonias of arthritic patients. In lymphatic and in arthritic subjects, *i.e.*, in subjects in whom are most often observed severe blennorrhagia and the generalized infections of this disease, the alkalinity of the blood is without doubt diminished, and the constant presence in it of uric acid is determined.—*Société Médico-Chirurgicale d' Anvers, Annales*, November-December, 1900.

Treatment of Vomiting of Pregnancy by Bicarbonate of Sodium.—M. F. Monin has had occasion to employ this treatment twenty-five or thirty times, and almost always with the greatest satisfaction. It is necessary to overcome constipation which is so frequently observed in women, and especially in pregnant women, and which favors the appearance and duration of digestive troubles. The writer believes that the vomiting of pregnancy is attributable to a disorder of the gastric secretions. The morning sickness in particular appears to show that the stomach of certain pregnant women secretes in a continuous and not in an intermittent fashion. Consequently, this treatment has been instituted; bicarbonate of sodium being given in large doses during the time when the stomach is empty, and the results have been most happy. Five cachets of gr. ii. have been given during the day to begin with, and these are increased in quantity as necessity indicates.—*Lyon Médical*, January 27, 1901.

Mercurial Injections in Syphilis.—A. Guérin, in giving the indications for this treatment, states that the practitioner will reserve the mercurial injection for syphilis of rapid evolution with early nervous and visceral complications and repeated recurrences. Everything that gives to the disease a character of gravity is a pressing indication. The injections are given to spare the stomach of the patient and for numerous reasons of convenience. Some patients refuse to take the ordinary mercurial treatment. Some writers believe that the injections ought to be instituted immediately after the diagnosis of indurated chancre. This treatment is contraindicated by the cachexia of tuberculosis or senility and by diabetes; it should not be given in cases of paralysis, varicosity, or œdema. It is especially contraindicated in albuminuria which is not the result of syphilitic nephritis.—*Journal de Médecine de Bordeaux*, January 27, 1901.

Some Reflections on the Treatment of Erysipelas.—E. Deronde states that mild erysipelas has a normal duration of seven or eight days and is cured without intervention; but it is not possible to make from a clinical point of view a prognosis of this affection. He reports five cases, four of which were treated with serum. From the history of these cases he concludes that the serum of Marmorek is curative; it arrests the progress of the streptococcus and causes the temperature to fall; its action is immediate and it is not disagreeable. The writer shares the belief of Landouzy that the severity and duration of the illness are both less in patients who are submitted to orrhotherapy.—*La Revue Médicale de Normandie*, February 10, 1901.

Berliner klin. Wochenschrift, Feb. 4 and 11, 1901.

A Case of Hysterical Sensory Aphasia in a Child.—By L. Mann. The patient was a girl aged seven years. No cause could be assigned for the peculiar condition except possibly a fit of anger during which she cried a great deal. The mother noticed that the child was apparently becoming deaf and that her speech was gradually becoming unintelligible. The animal functions in general seemed normal. Careful examination showed that the child seemed to have lost the power of attaching definite ideas to the sound of familiar words. After several months she was removed from home, taken to an institution, kept in bed, and given a course of cold packs and douches with faradization. At the same time an effort was made to teach her to pronounce properly words spoken by the physician. At first, treatment was without result, but an improvement finally began, and after a prolonged course of the plan above outlined, her speech became perfectly normal, as well as her hearing.

Tallerman's Apparatus.—By F. Neumann. The article is a description of the various forms of apparatus devised by Tallerman in 1893, for the employment of superheated dry air for the treatment of various painful affections. The contact of the hot air with the skin draws blood from the deeper parts to the surface, and so exercises a powerful influence upon the circulation. The author commends this method of therapy, especially in sciatica, arthritis deformans, lumbago, chronic joint rheumatism, cases of ununited bone fracture with circulatory disturbances, severe contusions of the pelvis and vertebræ, painful scars and tissue deformities after gunshot wounds, scleroderma, myxœdema, and cases of painful flatfoot. The method is not equally valuable in all of these conditions, and in some instances has entirely failed to give relief, but, generally speaking, it is a most valuable therapeutic agency, and, in cases of arthritis deformans, has succeeded better than any other plan of treatment. Clinical histories are given.

Observations on the Treatment of Puerperal Fever with Marmorek's Antistreptococcus Serum.—After some remarks upon the introduction of this method of treatment and its results up to the present time, the author gives his experience with nine cases of puerperal fever in which it was used. It is not indicated in every rise of temperature in puerperal infection, for it is of course useless unless this infection is due to streptococci. Consequently, its scientific employment presupposes the bacteriological examination of the lochia. Of the nine cases, the lochia showed in one purely anaerobic, gas-forming diplococci, in four a mixed infection, partly aerobic and partly anaerobic streptococci; in two absence of all micro-organisms, and in two pure streptococci. In the first case the injection of serum was without apparent result; of the group with mixed infection two were fatal; both of the cases with sterile lochia ended in recovery, as did also the two with pure streptococcus infection.

The Significance of Bodily Work in the Treatment of Nervous Diseases in Institutions.—By A. Erlenmeyer. The author's conclusions are in general as follows: Work as a method of treatment is unadvisable in cases of neurasthenia, and is often accompanied by an increase in the severity of symptoms. In patients who are simply nervous, it is a valuable and rapid method of benefit. In cases of those patients who manifest, in combination with their nervous condition, psycho-pathological evidences, the latter may be removed and in this way the general condition greatly ameliorated. In hysteria and epilepsy, bodily work generally has no influence upon the diseased condition. Work is inapplicable in general conditions of brain and cord lesions.

Observations on the Treatment of Puerperal Febrile Conditions with Marmorek's Antistreptococcus Serum.—By M. Blumberg. In this article the author gives in detail the clinical histories of the cases treated by him, the general features of which were discussed in a previous issue of the *Wochenschrift*.

Experience with the Tallerman Apparatus.—By O. Zimmermann. This is another recital of clinical observations, confirming in a general way the views of Neumann.

The Increase and Diminution of Hereditary Sensitiveness to Poisons.—By E. von Behring and Kitashima.

Hygiene of the Eye in the Nineteenth Century.—By H. Cohn.

Fatigue and Recreation.—By M. Verworn.

Deutsche med. Wochenschrift, Feb. 7 and 14, 1901.

Operating in the First Ether Anæsthesia.—P. Sudeck advocates the performance of minor operations, and even of those more serious in nature but which can be quickly completed, in the very first stage of anæsthesia produced by the inhalation of ether. This is not the usual so-called primary anæsthesia, but commences with the first deep inhalations of the vapor and lasts until consciousness begins to be impaired. It is of the greatest importance that the patient be fully impressed with the necessity of taking deep inspirations from the beginning, regardless of the pungent odor of the anæsthetic, and that he keep his mind occupied only with the details of the anæsthesia. For this reason it is advisable to keep him in ignorance of the fact that the operator is to begin work almost with the first inhalation, and all the instruments, etc., should be kept covered over until the last moment. The rationale of the method rests on two factors: first, the temporary overpowering of the pain-perceptive centres of the brain by the anæsthetic, and, second, the intense mental concentration required on the part of the patient to keep up the respirations in spite of the disagreeable stimuli produced by the ether vapor. Even operations of considerable magnitude can be painlessly performed in this way, such as amputations of thigh or arm, laparotomy and drainage of the abdomen for peritonitis, extirpation of diseased glands, etc., though it is of course especially adapted for less extensive procedures. The advantages of the method are its absolute safety, its lack of risk of secondary damage to the respiratory apparatus—since the quantity of vapor inhaled is so small—and the speedy recovery from narcosis, without any of the usual unpleasant after-effects. The essentials for success are the securing of the patient's undivided attention to the business of anæsthetization, and rapid, sure operating.

The Operative Treatment of Pulmonary Tuberculosis.—H. Sarfert says that while the modern tendency in the therapy of this disease is to lay almost the entire stress on early diagnosis, and to expend all efforts in the treatment of the cases of short standing, there are still many patients with advanced lesions who may be benefited by surgical intervention. Great care is necessary for the selection of such cases, and the number is not large, but under favorable circumstances good results are always to be expected. As a result of experiment on one hundred and fifty cadavers the author has evolved the following technique, which has proved feasible in actual practice. The cavities most accessible to treatment are apical ones, and may best be reached by resection of the second rib. The skin incision be-

gins at the sternal end of this bone and is carried outward about four inches. After the rib has been exposed the periosteum is incised and the bone freed, after which its cartilage is divided and the axillary end broken through. The parietal pleura is now to be separated from the chest wall by blunt dissection with the fingers, when the apex of the lung may be brought out of the wound without the pleural cavity having been opened. This manœuvre is greatly facilitated by the dense adhesions that always exist, so that there is little risk of producing a pneumothorax. The antrum is now located by palpation and laid open, either by incision or with the Paquelin cautery. Arteries which have been exposed by the disease may now be ligated, communicating cavities opened and made into one large one, and the suppurating surfaces cleaned and drained.

The Bacteriology of Acute Articular Rheumatism.—F. Meyer seems to have found the specific cause of this infection. After numerous attempts at finding bacteria in the blood or joint exudate of rheumatic patients had failed, he turned his attention to the angina often accompanying these cases, and obtained from the tonsillar mucus pure cultures of a characteristic type of streptococcus. Injected into animals, this produced local infiltration and necrosis at the site of injection, but no suppuration, differing herein as well as in other particulars from the growths obtained from the throats of patients with scarlatina, sepsis, influenza, tuberculosis, and muscular rheumatism. After a lapse of six to ten days, successive inflammations of various joints took place, with a serous or sero-purulent exudate from which no cultures could be obtained, while at the same time a slight febrile movement was noted. On post-mortem examination such animals exhibited accessory lesions closely resembling those found in rheumatic human subjects, viz., pericarditis, pleurisy, and peritonitis, while endocarditis with valvular vegetations—which before this has never been produced without preliminary injury of the valves—frequently resulted. The resemblances between the effects produced by this organism and the manifestations of acute articular rheumatism are so striking as to justify the belief that some etiological relationship must exist between the two.

A Method for the Differentiation of the Blood of Various Animals with Especial Reference to the Demonstration of Human Blood.—Uhlenhuth has found what appears to be the first reliable biological differential test for human blood. The principle of the method lies in the fact that by injecting into rabbits, at intervals of six to eight days, small amounts of the defibrinated blood of any other animal changes are produced in the rabbit's blood which cause it to give a reaction with the blood of that other animal alone and with no other. If a few drops of the serum of a rabbit that has been treated with ox blood, for example, are allowed to fall into each of a row of test tubes containing dilute solutions of the blood of various animals, absolutely no reaction is produced in any tube except that containing ox blood, which at once shows a slight turbidity which increases on standing and finally develops into a flocculent precipitate. Similarly, a rabbit that has received injections of human blood furnishes an infallible reagent for detecting human blood, even in very minute amounts. So far the blood of nineteen different animals has been successfully tested, as well as the blood of man, the horse, and the ox, scraped from a board and dissolved in salt solution after having been allowed to dry for four weeks.

A Contribution to the Understanding of Some Gouty Manifestations.—Adler regards the joints as safety valves in gout, whereby through the deposition of uric acid in their cartilages the blood is relieved of its excess of this material and the kidneys and vessels are saved a certain amount of damage. At the same time, various other unpleasant symptoms, such as diarrhœa, catarrh of the mucous membranes, sciatic pains, general malaise, itching of the skin, and cardiac difficulties are relieved, as is a common observation after acute attacks. On the other hand, if reabsorption of the gouty deposit be too rapidly caused by the use of remedial agents, decidedly unpleasant reactions on the part of heart and liver may result.

Observations on the Bactericidal Action of the High-Tension Spark and a Method for the Better Application of the Bactericidal Power of the Arc Light.—By H. Strebel.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENT OPENED—GERMAN MEASLES—POISONED FOOD AND BEER—PLAGUE AND RATS—CLINICAL SOCIETY—OBITUARY.

London, February 15, 1901.

All the week we have been occupied by events connected with the accession of our new sovereign and the prospects of the future. The interest and even excitement which put other topics aside culminated yesterday in the great pageant of the opening of his first parliament by King Edward VII., accompanied by his Queen. You will have learned all you care to know about it from your newspapers; so I will only mention that in his speech from the throne the King referred to some proposed domestic legislation of special interest to the profession, viz., public-health acts and water supply, factory and workshop law, the prevention of drunkenness, and literary copyright.

It seems a sad sequel to recent events that the King should be holding himself ready to start for the Continent to see his sister, whose condition is so serious.

German measles has become almost fashionable, and people are so styling a common cold, just as they often dignified it as influenza. The authorized statement on the Duke of York's recent illness shows that it was a severe attack, the temperature being 102° F. for six days before the rash appeared, with gastric pain, cough, slight friction sound at the left base, vomiting, etc., and on one night delirium. Though the attack was not dangerous, it was enough to show that German measles can be exceedingly unpleasant. The few of the public who thought too much fuss was made about the patient will now be satisfied and commend the doctors who insisted on proper care. As it is, perhaps he was exposed too early in the severe weather, for in consequence of a fresh cold he was unable to be present at the opening of parliament yesterday. The Princess Victoria also had to stop at home from the same cause.

Dr. Buchanan, who was sent to investigate the beer poisoning, for the local government board, has concluded the inquiry. His report does not add much to the information I have sent you, but he marshals a number of facts in a convenient form. The approximate number of cases in Manchester, where most occurred, he puts at two thousand, and the deaths at thirty-six, of which twenty-three were of women and thirteen of men. In both Manchester and Liverpool the epidemic grew rapidly between August and November, but within a short time of the announcement that arsenic had been discovered in beer it was practically arrested. Some of the victims drank large quantities; seven out of eighty-eight confessed to a gallon or more a day; ten others are classed as "heavy drinkers," though they were less definite as to how much they took; of the remaining sixty-one, several admitted half a gallon and one two gallons. Draymen at some of the breweries suffered exceptionally. But moderate drinkers did not escape, a number of them who took very little being attacked. Some of the brewers' expert committee told Dr. Buchanan beer would be condemned if their test showed arsenic in quantity of 1 part to 1,500,000.

There was an inquest on one of the cases at Liverpool on Tuesday, when the professor of chemistry at the University College (Prof. Campbell Brown) told the coroner of a calculation he had made which is startling the newspapers. Reckoning the distribution to extend over thirty weeks, he estimated from the amount found over four tons of white arsenic had been issued in beer—enough, if divided into equal doses and given at one time, to kill a million people in the week, or all the inhabitants of Great Britain in a season. Some fines have been inflicted for the sale of beer proved to contain arsenic, but it is obvious that these convictions are scarcely the best way of dealing with such a question.

There is a great outcry for legislation, and many are not willing to wait for the report of the government commission. I am not sure that the delay would be altogether unwise, as the commission is to inquire as to the contamination of other food products and we might in the end get a more extensive measure of protection as to the purity to what we eat and drink.

The appearance of plague at Cardiff, Hull, and Bristol has naturally caused some uneasiness, but the measures adopted have been successful. An active campaign has been taken against rats as the most dangerous vermin, but I doubt the propriety of offering a price for every dead rat, as it may lead to the handling of them by many people. You will remember that Cardiff had a case last October, and prevented the infection spreading. Hull, too, did well since then, and Glasgow is a fine object les-

son. These places and other ports are watching vessels that may have rats from infected places. Cape Town has to cope with a small epidemic, which it is to be hoped will be restricted to narrow limits. The appearance of the pestilence in various parts of the world, and the means of rapid communication in our days, may well suggest that we may witness a spread of the disease as extensive as epidemics of cholera or such as may rival the ravages of former outbreaks of the scourge. But at least we are better prepared.

At the Clinical Society, after the adoption of the address of condolence and loyalty, Dr. Nabarro read the notes of a case of pronounced "spleno-myelogenic leucocythæmia subsequent to an attack of malarial fever." The patient, a man aged twenty-three years, went to Vancouver in 1899, and there had "chills." The rigors lasted about one hour, were followed by a hot feeling about the head, and that by perspiration. Not getting his strength afterward, he returned to England and saw Dr. Thin. The patient told Dr. Pybus that when in Manitoba he stayed two days in a swampy place. Also he had at one time camped by a small creek where mosquitos swarmed. Dr. Pybus, practising in the district for ten years, had had only three other similar cases, and they were about two miles from the patient's house. On March 28, 1900, Dr. Thin found he had an enormous spleen, no parasites or pigmented leucocytes, but white corpuscles greatly increased. Dr. Nabarro saw him at Dr. Thin's house and examined the blood. There was great diminution of the percentage of lymphocytes (twenty to thirty per cent.) and a corresponding increase of myelocytes (twenty-eight to forty-two per cent.). Many transitional forms were seen. The spleen remained large but caused no inconvenience, and, in spite of marked anæmia and the large number of white corpuscles, the patient seems to enjoy a fair degree of health, as he feels able and wishful to follow some occupation.

The next part of the programme was "instantaneous radiography," taken up by Mr. E. W. Shenton, who said the term was applied to *x*-ray photographs taken by exposures reduced to the lowest reasonable limits, say from a mere fraction of a second to thirty seconds. By the aid of large *x*-ray tubes he was able not only to reduce the exposure but to show the deeper parts of the body on the screen, a great advantage in detecting renal calculus or exactly locating and removing foreign bodies. He showed a number of examples of his work which were much admired. The president (Sir D. Powell) remarked on the promise afforded by the method in mediastinal and other growths.

Dr. Batten said he had used *x*-rays largely but had not met with such a complete installation nor such clear results with such brief exposures. He thought Mr. Shenton had hardly done himself justice in not giving more details of his method, for it depends on details to obtain such fine results.

Dr. Hugh Walsham referred to the question whether such short exposures are desirable in cases of pulmonary phthisis, and said photographs sometimes revealed points not clear on the screen.

Dr. C. Williams asked about dermatitis and Dr. Eastes whether the retinæ were affected.

Mr. Shenton, in reply, said in each case there was a correct exposure, and error either way would mar results: photographs should be used to confirm the screen. He had seen nothing of dermatitis except on his own hands, and had no knowledge of any effect on the retina.

Among the killed at Modderfontein was Civil Surgeon Allan Walker, who is stated to have received three bullet wounds and then been dispatched by a Boer. He was only twenty-six years old.

Dr. A. H. Jones, physician to the Northampton Infirmary, died after a few hours' illness. He was only forty-five years of age. He was M.D. of the London University and author of an interesting "Historical Sketch of the Physicians and Surgeons of the Northampton Infirmary in the Last Century," published in 1895.

CLINICAL SIGNIFICANCE OF DULNESS IN APPENDICITIS.

To the Editor of the Medical Record.

Sir: My attention was called by one of your subscribers to Case VII. in my article on "The Clinical Significance of Dulness in Appendicitis," in which case I attribute to hydrogen peroxide the cause of the fatal result, while in the same issue, under Surgical Suggestions, Robert T. Morris considers hydrogen peroxide the "sheet anchor" in appendicitis.

Not for a moment would I think of refuting the statement of so eminent an authority as Robert T. Morris, yet I have every reason to believe that there is danger in the routine use of hydrogen peroxide in appendicitis. I cannot present a more cogent reason than to detail my experience in this particular case. The walls of the abscess cavity were frail and weak, and in detaching the adherent appendix, though it was easily accomplished, I necessarily weakened the wall at that point still more. The case did well up to the eighth day, and on this occasion the hydrogen peroxide did not escape so freely as it had at the previous dressings. The temperature commenced to rise, and within forty-eight hours the patient succumbed to suppurative peritonitis. Post-mortem revealed the intestine in which the stump of the appendix had been invaginated, in a normal condition, but there was evidence of a rupture of the wall of the abscess cavity and the peritoneal cavity was filled with pus.

The reaction resulting from the combination of the hydrogen peroxide with the pus caused a gaseous distention of the abscess cavity, and the point of drainage being too small to allow the free discharge of the pus, the cavity became overdistended, resulting in a breaking at a point of the least resistance, thus allowing the pus, if even a drop, to discharge into the peritoneal cavity.

February 23, 1901.

RECKLESS DRIVING OF AMBULANCES.

To the Editor of the Medical Record.

Sir: The needless hurry of our ambulances on many of their calls often imperils public safety. The writer witnessed on Sunday afternoon on Fifth Avenue, when crowded with pedestrians and vehicles, an instance of this.

There came charging down the street an ambulance with clanging bell, the horse on a plunging gallop. From a cross street a baker's wagon passed through the line of carriages almost in front of the ambulance, whose driver, to avoid a collision with the wagon, pulled sharp up to the left, crowding aside the horses of a conveyance coming up on the right side of the roadway, his forewheel hub overriding the carriage hub, and thus luckily avoiding another smash, then on to the pavement to the dismay of the passers-by, who scattered in all directions. With a yell, this Jehu then swung around to the right, and, ringing his alarm with all his might, started after the offending wagon, at top speed. The interne in the rear of the "bus," to encourage, cried, "Yes, go after him," settling his cap to enjoy the fun. Overhauling the baker's wagon in the middle of the block, the driver pulled up, came down from his throne, and assailed the obstructor to an errand of mercy, while his horse rested from the labors of his attempt to annihilate the bread wagon, the carriage, and the unlucky pedestrians. After a tirade, breath having been recovered to a degree all around, the ambulance trundled off and five hundred people who had collected, interested in what might have occurred, streamed away. Ten minutes later the ambulance, returning with the patient, passed with rush up the street. Looking into the matter, I learned that the case was that of a patient who had sustained a "laceration of the arm; there had been bleeding, but as the doctor who went out on the call was from the medical side, he didn't know if it was a compound fracture or not. The case was in the house, and the chief was to see it when he called." The writer remembers, not so many years ago, when he, in a neighboring city, delighted in an ambulance with a monster gong which gave one plain clang for each pull, a well-trained horse, an extra jump in response, and the doctor sat in front in state, taking in mangled fingers, typhoid-fever cases, and plain "D. T.'s," on the run.

Recalling these happy days, he doesn't want to scold, but to have the ambulance drivers instructed from time to time that the doctor is in absolute charge of the ambulance when on the street.

Trolley cars and heavy trucks have little respect for ambulances, and it is due to the public's knowledge that there isn't always need for such a hurry for that ambulance which seems to be so active that the back gets there first; not but what despatch is needful at times. A carbolic case wants attention quickly. To pull a cut throat back from the grave depends often enough on the ambulance surgeon. The writer believes the value of this strong arm of the service will be enhanced if some of the senior's other duties be lightened, and be given "first call" on ambulance duty, the senior assistants taking subsequent calls, so that the incoming junior may be relieved until the last of his term of the most difficult yet valuable work of his service. The obliging officer will tell when sending in the summons if time is a factor, and, indeed, most calls come in telling what has happened before telling where the happening has taken place, so the doctor knows when haste is expedient on crowded thoroughfares. If speedway gaits are confined to quiet streets when returning from Bellevue and on cases of little importance, the public will soon learn to give way to the ambulance, be it drawn by horse or propelled by the better controllable auto power.

Frederic Griffith, M.D.

805 Madison Avenue.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 18, 1901.

PARKER SYMS, M.D., PRESIDENT.

Ulcer of Placenta; Severance of Umbilical Cord before Birth.—DR. EDEN V. DELPHEY presented this specimen, which had been removed from a woman thirty-two years of age, pregnant with her fifth child. She stated that when seven months and a half pregnant, and while hanging up clothes one morning at 11 o'clock, she had suddenly felt what she described as "a great commotion in her abdomen." This had been followed by labor pains, and by 6 o'clock that evening there had been slight dilatation of the cervix. At 10:30 P.M., the uterus being in a state of tonic contraction, Dr. Delphey had ruptured the membranes, performed manual dilatation, and delivered with forceps a fœtus that had presented in an occipito-posterior position, and had been dead a few hours. When the umbilical region had come into view he had been astonished to find only a stump of umbilical cord, measuring three-fourths of an inch in length. The placenta was delivered spontaneously. Its surface was covered with old clot, and there was an ulcer on the maternal side, about one inch in diameter. The cord was fourteen inches long. Two hours after delivery, the mother had gone into collapse, with symptoms of internal hemorrhage, and had died at 5:30 P.M. The pathologist reported that the ulceration represented a broken-down gumma, and that the end of the cord showed productive inflammation. The rupture could be accounted for only by traumatism.

Lack of Uniformity in Prescribing Myopic Glasses.—DR. S. BUSBY ALLEN, the author of this paper, drew a vivid picture of the great evils flowing from the careless or improper fitting of glasses to the myope, resulting oftentimes in great mental deterioration and the blighting of a life. He said that while all agreed that the strain of convergence was the chief trouble, there was not so much agreement upon the effect of accommodation. In myopia the accommodation could be used only when there was a previous excessive effort at convergence. When there was a variation of more than one diopter there was a necessity for glasses for near work.

DR. H. OPPENHEIMER said that at birth the eye was not myopic. The myope was not primarily a perfectly rugged person, and hence the importance of keeping such children at outdoor sports, and avoiding as far as possible the use of the eyes. If these little ones could be prevented from reading in a bad light, or with the head down so closely as to give rise to congestions, or reading in bed in such a position as to cause congestion of the vessels of the neck, much could be done toward preventing myopia. He thought oculists had gradually come to the conclusion that if the effort at convergence could be corrected, a great deal could be done toward securing comfort for the myope. The tunics of the eye were apt to become stronger and firmer after puberty, hence the great importance of attention in early life to the general regimen. When there was a high degree of myopia, the necessity for extreme convergence was done away with by the removal of the lens.

DR. FRANK SKEEL said that the author of the paper had not overdrawn the picture. It was the teacher, and not the parent, who ordinarily first called attention to a defect in the vision of a child. It should be remembered that no two cases of myopia were exactly alike, and hence every case should be treated by itself. This explained the apparent lack of uniformity in prescribing for these cases. It was his rule to prescribe overcorrection in a moderate degree of myopia—say, above seven and below nine. For high myopia, very little could be done. For low degrees of myopia, he prescribed a glass fully correcting the error. When the eye was beginning to get more myopic, he frequently kept it under the influence of atropine for a month or six weeks, or perhaps longer. A case was cited in which, although no effect had been observed from the use of atropine for four weeks, at the end of two weeks more the vision had been wonderfully improved. These cases should be kept under observation, being seen at least twice a year.

DR. J. H. WOODWARD said he could not agree with the reader of the paper that an effort of accommodation would cause true myopia, although admitting that it would give rise to an apparent myopia. The prevention of myopia was certainly a very important matter, and one of the best means of accomplishing this was by the correction of slight degrees of myopia very early. If the act of accommodation caused myopia, then our mainstay was taken away. In moderate degrees of myopia he thought it was the consensus of opinion that glasses for distance should be worn also for reading. The reason for this was that the muscles for accommodation were in this way strengthened. The reason that so many children wearing glasses were seen at the present time in the streets was that they were overworked at school. Little tots might be seen coming home from school with as many books as they could very well carry.

DR. J. HERBERT CLAIBORNE said that for many years he had been treating myopia on the principle that it was not so much the result of a strain of the muscles of accommodation as of pressure of the lateral muscles. He thought it was reasonable to assume that in the shape of the eye there was such a thing as perfection, and he could not agree with those who held that emmetropia was a stage in the direction of hypermetropia. Instead of overcorrecting myopia, as had formerly been the custom, it had been his practice to correct fully in youth, giving as nearly as possible perfect distant vision. In the cases of those under the presbyopic age, he gave a complete correction, the glasses being worn both for near and for distant work. He had found that there was still a large number of practitioners who would give to persons under the presbyopic age a glass for distance and another for reading. He could not see the logic of such practice. At least in a moderate degree of myopia, he believed in correcting the error of refraction completely, giving the best possible distant vision with the weakest glass. The patient should be instructed to use this glass not only for distance but for reading. At first, it might seem almost impossible to educate the accommodation to this new state of affairs, but it was perfectly feasible. The person should be directed to read for fifteen minutes the first day, for half an hour the second day, and to add a quarter of an hour daily, until reading for two or three hours each day. The correction of myopia in presbyopes presented a very different problem.

A New Operative Method of Exposing the Seminal Vesicles and the Prostate for the Purpose of Extirpation or Drainage—a Preliminary Report.—DR. EUGENE FULLER read this paper. He said that the thighs should be flexed sharply as in the extreme lithotomy position, and then the patient put on the Trendelenburg table, belly downward. It was generally better to put the patient in this position after having been placed under the influence of the anæsthetic. The external incision consisted of two somewhat converging longitudinal cuts, connected at their proximal extremities by a transverse cut. The author

then described in detail his method of reaching the seminal vesicles through these incisions. He said that the prostate was exposed in this way most satisfactorily; not that he would advise it for such cases, however, because of his belief that the usual method secured far better drainage. He reported five cases treated by the new method. In some of these there had been for a long time an obstinate frequency of micturition, which had not yielded to various cystotomies. Relief had been afforded by incision into the seminal vesicles, curettage, and gauze drainage.

Dr. F. Tilden Brown said that he had been very favorably impressed with the free access to the seminal vesicles obtained by the method of Dr. Fuller. One of the cases reported had been referred by him to Dr. Fuller. Prior to the operation there had been an exquisitely sensitive area along the base of the bladder, and the patient had suffered from very frequent micturition. This sensitiveness had disappeared since operation, the urination was very much less frequent, and there was no longer the annoying delay that had been formerly experienced in beginning the act.

A Contribution to the Bottini Operation for the Radical Relief of Prostatic Obstruction.—Dr. L. Bolton Bangs read this paper (see page 367).

Dr. Willy Meyer said that he had operated upon thirty-nine cases, and in about seventy-five per cent. of these gonorrhœa had been present. This was interesting in connection with a very recently published paper in which it was declared that there was reason to believe that gonorrhœa was largely responsible for the occurrence of prostatic enlargement. The presence of a calculus could be determined by carefully manipulating the beak of the instrument in the bladder just before the operation. It was most desirable to refrain from using local anæsthesia in sensitive patients, yet it was worth remembering that if two-thirds of an ounce of a two-per-cent. solution of cocaine were mixed with one ounce of a three-per-cent. solution of eucaine, the local anæsthesia would be much more satisfactory than with a solution of either one alone. The principal pain arose from the hugging of the gland. When the kidneys were normal he had used either general anæsthesia or spinal anæsthesia. He had used the latter in five cases, and had been delighted with it. He was of the opinion that the depth as well as the breadth of the incision was important, and hence, in some instances, had immediately repeated the posterior incision. The after-treatment should be conducted most carefully. As the pain following the operation was often intense, he made it a rule to insert immediately after the operation a smooth Mercier catheter and to retain it in position. If the urine were kept loaded with antiseptics, the method was really one of continuous antiseptic irrigation. Some of his patients had retained this catheter as long as thirty days. This practice had been severely criticised, but he was confident that it was a valuable procedure. There could be no doubt that the prostatectomy was the more surgical procedure, and its after-treatment was much less difficult and arduous than that of the Bottini operation. It would be the operation, in all probability, for most of the cases of hard, firm prostate, and for those so-called soft prostates having a hard nucleus, which allowed of their being enucleated without great difficulty. The cases of soft prostate were amenable to cure, but not, he thought, by prostatectomy.

Dr. Eugene Fuller said he was one of those who had been steady adherents of the operation of prostatectomy. The results that had been reported from the Bottini operation had not been so very good that he felt tempted to change from prostatectomy to that operation. If the cases were carefully selected, these results would be decidedly improved. He feared that relapses would occur in the cases operated upon by the Bottini method, because of cicatricial formations. His chief objection to the Bottini operation was the burning through the tissues of the bladder to reach the prostate, and the probable extensive injury done to these tissues. In many of these prostatics the bladder was so diseased that a long rest was demanded in order to secure the full measure of relief. After the Bottini operation the desired surgical rest of the bladder could not be secured.

Dr. John Rogers said that his limited experience had impressed him with the safety of the Bottini operation as compared with the operation of prostatectomy, though the latter operation yielded certain and positive results. A case was cited showing the feasibility of doing a prostatectomy after a Bottini operation, should the latter prove insufficient.

Dr. J. W. S. Gouley expressed the opinion that the selection of the operation to be performed upon the prostate should be based upon an exact diagnosis. Mercier had failed in his prostatotomies and prostatectomies in cases in which there had been any considerable enlargement of the supramontanal folds. These operations had been singularly free from hemorrhage. Bottini had taken his cue from Mercier, but he had tried to do too much. The Bottini operation seemed to the speaker to be distinctly contraindicated in cases in which the so-called third lobe projected two or three centimetres into the bladder, for in such cases it could be hardly expected to accomplish very much. Dr. Gouley said that he had introduced Mercier's operation into this country in 1878, and had done about fifteen of these operations. In only one of them had he experienced any trouble from hemorrhage. When the prostate was very large, soft, or hard, the operation of prostatectomy was the one indicated. He believed its dangers had been exaggerated. Unfortunately its mortality had been due to ascending pyelonephritis. He had carefully dissected about one thousand prostates after death, and the really hard prostate, containing phosphatic concretions visible to the naked eye, had been a decided rarity. He saw no advantage in the Bottini operation over Mercier's first operation.

What the Bottini Operation Really Does.—Dr. S. Alexander thanked Dr. Bangs for his paper, which, he said, had brought out some entirely new facts, besides presenting a perfectly fair statement as to what the operation did in the hands of the skilful surgeon, and the difficulties met with under such conditions. He had also shown that this operation was not always successful, and that it required a longer convalescence than he had been led to believe from any other article written on this subject. The speaker went on to say that Bottini and subsequent writers had claimed that Bottini's operation burned a groove through the obstructing portion of the prostate, that the action of the cautery extended to a zone beyond the original cut, and that this never contracted, but remained open as a groove, and, consequently, overcame a mechanical obstruction to urination. Dr. Alexander said he noted that this claim had not been made in the paper just presented, because its author knew that this was not true. The author had stated that he had seen contraction of fibrous tissues, the result of a burn, and not the formation of a permanent groove. Dr. Alexander said that through the courtesy of Dr. Bangs he had had an opportunity of looking at a post-mortem specimen taken from a case in which Dr. Bangs had secured a brilliant success from the Bottini operation. Scars, the result of contraction, could be found in this specimen, but no grooves. No operation could be generally accepted by surgeons unless founded upon the anatomy of the part and a knowledge of the pathology of the condition for which it was done. There were anatomical facts which were not generally

appreciated, though they had been described by others, which were of vast importance in this connection. When a prostatectomy was done, the whole prostate was not taken out, but only those parts which caused the obstruction. He was free to confess that the operation of prostatectomy which went by his name was a most dangerous and difficult operation, and he was disposed at the present time to discuss the failures rather than the successes. He wished to say that the operation was not founded on any false principle, but that the bad results had depended upon a bad technique and our imperfect knowledge. It should be remembered that almost all of his patients had been very old men. Bottini's operation he considered to be a most valuable form of prostatotomy in appropriate cases, but it might be made a much more valuable operation if more attention were given to the kind and location of the obstruction. He urged that those who were doing the Bottini operation should get rid of the idea that all obstruction in the prostate was intravesical, and remember that the principal cause of obstruction was not intravesical, and that, hence, cystoscopic examination and examination with the searcher could not give all of the desired information.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, February 19, 1901.

JOHN H. HUDDLESTON, M.D., CHAIRMAN.

THE evening was devoted to the discussion of pleurisy.

Cyto-Diagnosis; its Applicability to Pleurisy.—DR. JAMES J. WALSH presented this paper, which, he said, was founded on the work of Widal. By an exploratory puncture this investigator obtained a few cubic centimetres of the pleuritic exudate, and centrifugalized the fluid. The cloudy portion should be spread upon a glass slide, but should not be subjected to pressure with the cover glass, as this tended to drive the cell elements to the periphery. The pleuritic exudate was characterized by the presence of small lymphocytes, which showed a tendency to run together. There were also a few amorphous bodies, which stained badly. When examined early, the multinuclear cells present were more numerous than in the later stages. The disappearance of the multinuclears indicated that the resisting-power of the tissues had been weakened. The exudate of mechanical pleurisy was characterized by the presence of "patches" of endothelial cells. In pleuritic fluid containing the streptococcus, multinuclears were found, showing the attempt at resistance, while their degenerated appearance showed that the resistance had been unsuccessful. Pneumococcus pleurisy furnished a very characteristic cell formula, according to Widal. It was characterized by the presence of a few red blood cells, some scattered lymphocytes, and a good many large uninuclear cells, some of which were veritable macrophagocytes. It was very rare, however, to find all of these cells together. In pleurisy, occurring some time after pneumonia, no pneumococci were found, and yet the cell formula of pneumococcus pleurisies would be found.

The Bacteriology of Acute and Chronic Pleurisy.—DR. ALEXANDER LAMBERT discussed this subject. He said that at one time it had been believed that all primary effusions in which no bacteria were found in the smear from the effusion were due to tuberculosis, but this was no longer considered tenable. About thirty to forty per cent. of all primary effusions were now known to be due to tuberculosis. The injection of the centrifugalized fluid into an animal would show the tuberculous nature of the case in a much larger proportion than would smears. Rheumatism had been given by many authors as the next most frequent cause of these effusions. Syphilis was also a not uncommon cause. A pneumococcus effusion was not at all uncommon, and was often purulent. Pleuritic effusions were quite frequently met with in cases of epidemic influenza, and were often complicated by the presence of streptococci.

The Treatment of Pleurisy with Consideration of Early and Late Tapping.—DR. C. E. NAMMACK read a paper with this title (see page 373).

The Use of Methylene Blue Injections in Pleurisy with Effusion.—DR. C. H. LEWIS read this paper, describing the method which he employed in some cases of pleurisy with effusion. His first paper on this subject had been presented about one year ago, and had been based on an experience in twenty cases. In his experience, spontaneous absorption by the lymphatic stream seemed to give permanent results. It had occurred to him that if some substance could be introduced into the pleural sac, which would give rise to the formation of adhesions, subsequent aspiration would result in a prompt cure. After some study he had at last selected methylene blue—a substance which was antiseptic, anodyne, and diuretic. It was important, he said, that the substance so introduced should be in perfect solution and that it should have the same specific gravity as that of the pleuritic effusion; also that the quantity of fluid in the chest should remain unchanged. It was best to dissolve the dye in the effused serum. It had been proved that the respiratory movements were sufficient to cause a proper mixing of the fluids. The serum could be drawn into a graduate, mixed with the methylene blue, and returned to the cavity. He had employed this treatment, with some variations in the technique, in twenty-four cases of pleuritic effusion, including one suppurative case. The average duration of treatment for the twenty-three sero-fibrinous cases had been fourteen days. So far as could be determined, internal remedies had no influence upon the absorption of the exudation. The shortest time for the appearance of the methylene blue in the urine after the injection was one hour. Ordinarily, ten to fifteen grains of methylene blue were employed.

The Routine Treatment of Pleurisy at the Mount Sinai Hospital.—DR. JULIUS A. BECKER read this paper. He said that the treatment of pleurisy following rheumatism was entirely antirheumatic. In pleurisy associated with septicæmia, Credé ointment, antistreptococcus serum, and setons had all been tried, but without benefit. In the pleurisies accompanying the exanthemata the treatment had been entirely symptomatic. For the pain, the Paquelin cautery, guaiacol, blisters, and strapping had been used locally, and morphine, codeine, or heroin internally. For the serous pleurisies, catharsis had been used, preferably in the form of drachm doses of Epsom or Glauber's salt, repeated every half-hour for eight or ten doses. A review of the cases of serous effusion treated at the hospital showed the striking benefit from aspiration practised as soon as there was evidently much interference with the action of the lung. In almost every instance the pulse had been improved in both quality and rate by aspiration. When the fluid had been rapidly increasing, there had often been no tendency to reaccumulation. The duration of the disease had been shortened by early aspiration, and after a cure had been effected there had been less thickening of the pleura and less crippling of the lung. The greatest number of aspirations during the past five years that had been practised on a single case of non-tuberculous pleurisy, in which a cure had been effected, was four. The occurrence of pain, coughing, or of a little blood in the fluid withdrawn, indicated that no more fluid

should be evacuated. In the many hundred aspirations hardly an accident had been recorded. In no case had there been a severe hemorrhage nor had an empyema been distinctly traced to infection from an aspiration. In large purulent effusions, the fluid should be removed by aspiration before operation, in order to avoid the danger of death from shock resulting from the sudden removal of a large quantity of fluid.

Conservative Treatment for Small Effusions.—Dr. M. Manges said that it was unfortunate that the majority of the sero-fibrinous forms were sterile of organisms; hence apparently the great importance of the labors of Widal, so graphically described in the first paper. He hoped the method would yield the results claimed for it, yet he feared the picture given was too bright to be exactly true. In spite of the obvious dangers of aspiration, if judiciously employed it certainly held out the best chances for recovery. The removal of the whole quantity of fluid was entirely unwarranted, as it was well known that the evacuation of a small quantity was often all that was necessary. It was possible that the presence of small quantities of fluid in tuberculous cases was not an unalloyed evil, and one should be slow under such conditions to resort to aspiration. The records of the deadhouse showed that there was danger of injuring the lung with the point of the needle, and he had himself seen death result in one instance simply from the aspiration. He would caution against rashly deciding to aspirate in cases having only small effusions.

The Surgical Treatment.—Dr. H. Lilienthal advised, as a routine treatment in cases in which the chest was to be tapped, that the skin be nicked with a knife before the introduction of the needle. This would prevent skin infection and made it less likely that the needle would become plugged. He was of the opinion that the cases reported by Dr. Lewis, in which methylene blue had been tried, were too few to prove anything, especially as he understood that no special control tests had been made. It was not impossible that a similar result would have followed the introduction of an indifferent fluid or of some gas like nitrogen. With possibly the rare exception of a typhoid empyema, the safest thing was to operate as soon as the pleural cavity was found to contain pus. He had seen empyema occur secondarily, by direct extension from suppuration in neighboring organs. He had seen an abscess in the vermiform appendix extend up until it became subphrenic, and finally lead to an empyema of the pleural cavity on that side. He had recently seen a case of staphylococcus empyema resulting from an osteomyelitis and general infection of the blood with staphylococci. The drainage tube should not be inserted any farther than was absolutely necessary; in bad cases it was better to resect the ribs and make such a large opening that no tube would be required. He favored the use of Koenig's method of postural drainage after such operations. After the injection of saline solution into the pleural cavity, the patient should be turned into that position which would cause the evacuation of all this fluid, and the nurse then directed to place the patient in this position for a short time, at intervals of a few hours. The dressing should be bulky. The position varied a great deal; sometimes it was almost a sitting posture, while in other cases it was necessary nearly to invert the patient.

Possible Deleterious Action of Methylene Blue.—Dr. S. S. Burt said that he had met with cases which had done very well without much medicine, but he had used the aspirator very freely. There were some cases in which it was difficult to be sure of the presence of fluid in the chest, but in most instances one who was expert in physical diagnosis should be able to make the diagnosis without resort to exploratory puncture. The latter procedure was chiefly useful for determining the character of this fluid. It had been his practice to aspirate the fluid until the appearance of the patient and the discomfort produced indicated to him that it was time to desist. He was greatly interested in what he had heard regarding the methylene-blue treatment, but had been a little afraid to try it because of the injurious action it was said to have on the kidneys. In the *American Medico-Surgical Bulletin* for December 15, 1895, would be found an account of experiments on animals, to determine the effect of this substance on the kidneys and other organs. The conclusion there expressed was that methylene blue produced acute parenchymatous degeneration of the kidneys and liver, hyperæmia of the spleen, acute catarrh of the bladder, and a pronounced increase in the number of the white blood corpuscles.

Simple Method of Expanding the Lung.—Dr. Andrew H. Smith said that the word "pleuritis" had not been used this evening, which he took as perhaps an unconscious recognition that only two activities were present, viz., the attack of a noxa upon the tissue of the pleura, and the protective and reparative action of the structure attacked. No third activity, such as so-called inflammation, was mentioned even by implication. Nothing could be more indicative of the passing of "inflammation," which he firmly believed to be the monumental event of the first quarter of the new century in the field of pathology. Unless septic symptoms were present, it seemed justifiable in many instances to temporize before aspiration of the chest was resorted to. It had seemed to him that very often the use of a short tube in the chest, and the exercise of some patience, would secure far better results than were commonly observed from drainage with longer tubes. A patient recovering from pleurisy should be instructed to close the nostrils and make a gentle effort at expiration. The effect of this was to cause a gentle expansion of the diseased lung, entirely under the control of the patient. He should be instructed not to keep it up if pain were produced. It was a method which could be used without apparatus and, if need be, a hundred times a day—in fact, it was Nature's way. He had been surprised at the immunity of the other organs to tuberculosis in the presence of a tuberculous pleurisy.

Pleuritic Effusion in Tuberculosis a Conservative Process.—Dr. Henry P. Loomis thought it was quite difficult at times to diagnose small pleuritic effusions without the use of the needle, though theoretically it should be easy. He made frequent use of the hypodermic needle, and had never seen any harm result from it. Attention was called to the fact that often one of the best things that could happen in a case of pulmonary tuberculosis was the occurrence of a pleurisy with effusion, and hence one should be slow to interfere with it. He was of the opinion that such an effusion acted by keeping the lung quiet. He had used methylene blue in doses of forty or fifty grains a day in cases of malaria, and had never observed any injurious effects from it.

The Medical Treatment.—Dr. Egbert H. Lefevre said that he had made some experiments to determine the value of cyto-diagnosis, and felt compelled to say that he had not seen the beautifully clear pictures described by Widal. It was possible that he might succeed with a better technique. When one recalled the relations of the pleura to other organs, and the fact that it had no independent blood supply, he thought it must be evident that pleurisy was necessarily secondary. Some years ago he had suggested a line of experimentation to determine the effect of introducing minute particles of India ink into the trachea of animals. It was found that in a marvellously short time these particles of pigment found their way into the

lymphatics and were deposited underneath the pleura. In no case was any free pigment found in the pleural cavity. In tuberculosis of the lung there was ordinarily an early involvement of the pleura, but no true involvement of the free surface of the pleura. In the treatment of pleurisy he thought the ordinary respiratory movements on the affected side were very important. Long before the outpouring of fluid there was restricted motion. With the beginning of motion on the affected side absorption commenced. He had a very high opinion of the salicylate of sodium in causing absorption of the fluid. The original experiments with this drug on animals showed that, after a certain quantity had been given, the remedy was found not only in healthy but in diseased serous cavities. It was surprising how very frequently there was involvement of the pleura in conjunction with acute articular rheumatism. After trying many local applications, he had found the best results were obtained from inunction with blue ointment.

Hæmoptysis from Exercise after Pleurisy.—Dr. William H. Thomson said that pleuritic adhesions by persistent local irritation led to more pleurisy. Cases were cited showing that hæmoptysis was apt to occur quite independently of tuberculosis, and even long after an attack of pleurisy, simply as a result of physical exercise, particularly of a kind which caused motion of the arms over the head. It was well, therefore, to warn patients recovering from pleurisy against the danger of such exercises. His rule was to advise his patients to produce immobility of the affected side of the chest by strapping, for at least six months after the attack of pleurisy. In some cases of most obstinate and distressing cough following pleurisy, prompt relief would follow this strapping of the chest. He made it a rule not to remove more than eight or ten ounces of fluid from the chest by aspiration. Regarding the mechanism of dropsy, it was generally conceded that at the present time we were entirely ignorant; we had no accurate knowledge of the process of osmosis as it occurred normally during life.

Dr. Lambert remarked that there was on record a case of primary pleurisy in which at autopsy pure cultures of the typhoid bacillus had been found, without intestinal lesions.

Dr. Nammack said that the only case in which he would hesitate to recommend prompt evacuation of the pus in empyema was that in which the patient's condition was so low that even simple incision would prove very dangerous. He wished emphatically to dissent from the view that in all cases a diagnosis of pleuritic effusion could be made without the use of the needle.

Dr. Lewis said that in his cases the urine had been examined daily, both chemically and microscopically, and no deleterious effect on the kidneys from the methylene blue had been noted. He had not used the large doses spoken of by Dr. Loomis, but believed it was innocuous. He knew that methylene blue promoted the formation of fibrin, because he had seen this effect in cases of peritonitis, ascites, and hydrocele.

Dr. J. A. Becker reported a case of marked improvement following aspiration, even in the presence of tuberculosis.

Heart in Acute Rheumatism.—Rest in bed for a sufficiently long time is the most important part of the treatment of the cardiac manifestations of the disease. The occurrence of endocarditis, pericarditis, or myocarditis, or the previous existence of a valvular disease, whether compensated or uncompensated, is no contraindication to the use of the salicyl compounds, but rather an index to push their administration to overcome the toxæmia of the disease.—Delancey Rochester.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 25, 1901.

George B. Fowler, M.D., President.

The Prophylaxis of Venereal Diseases in this City: Medical Aspects of the Social Evil.—Dr. Prince A. Morrow read a paper with this title. He said that medical men took alarm at the spread of smallpox, cholera, and similar diseases, but were apathetic in regard to the constant presence in their midst of syphilis and other venereal diseases. It had been estimated by a competent authority that fully one-eighth of all human suffering could be traced to venereal diseases and their results. According to Neisser, the discoverer of the gonococcus, gonorrhœa was, with the exception of measles, the most widespread of diseases. Fournier found, as a result of a painstaking personal investigation extending over several years, that upward of one-seventh of the population of Paris was syphilitic. Venereal morbidity could be best estimated by studying the records of large bodies of soldiers. Thus, out of 68,331 British soldiers stationed in India, the admissions to the hospital for venereal disease were 36,881, or 53.7 per cent. Of this number, 25.9 per cent. were cases of syphilis. While venereal diseases were rarely fatal in their immediate effects, they contributed largely to the general mortality, by their ultimate results. Within recent years our knowledge of the pathological relationship of gonorrhœa to many morbid states of the human system had been greatly amplified, so that this affection had risen to the dignity of a public peril. Staining and culture experiments had demonstrated the presence of the gonococcus in the pleura, endocardium, pericardium, the blood-vessels, tendons, tendon sheaths, etc. Some German authorities stated that eighty per cent. of all the deaths from uterine diseases were from affections of gonorrhœal origin. Again, blennorrhœa neonatorum contributed to our blind asylums from ten to twenty per cent.—an appalling number, but not nearly so great as in former years when the prophylactic method of Credé was not in vogue. That our conception of syphilis had entirely changed was evident from a comparison of the modern text-books with those of former times. The great prominence given to visceral syphilitic lesions was especially noticeable in our modern works. Syphilis of the brain and cord occupied, in the tertiary manifestations, the first rank in frequency as well as in gravity. The frequency of marital syphilis was not generally known, or even suspected. During the past year he had carefully investigated this matter in every dispensary case coming to him. Fully seventy per cent. of his cases of syphilis appeared to have been of conjugal origin. Physicians, surgeons, and accoucheurs were much more liable to infection with syphilis than was supposed; he had seen no less than fifty such cases himself. Statistics showed that from sixty to eighty per cent. of all syphilitic pregnancies terminated in still-born children. Rickets had its almost exclusive etiology in syphilis. The predisposition to abortion induced by syphilis might be made manifest even in the third generation. No disease had such a devitalizing influence on procreation as gonorrhœa; no disease had such a murderous influence on the offspring as syphilis; they literally poisoned the fountains of life.

Continuing, the speaker said that at the present day the extermination of every contagious disease was the watchword of modern sanitary science, yet there was not a single city in the United States in which these diseases were subjected to sanitary supervision. The syphilitic was twenty times more active as a disseminator of contagion than the consumptive, and yet how

energetic had our sanitarians been of late in endeavoring to control consumption while totally ignoring venereal diseases! Statistics showed that the average age at which syphilis was contracted by women was from eighteen to twenty, and for men, twenty to twenty-five. The present policy of inaction seemed to be a confession of our inability to deal with these dreadful scourges of the human race. It was probable that sanitary authorities were largely deterred because of the strong public sentiment against the legal restriction of prostitution. The law had taken cognizance of certain forms of prostitution, but certain forms of the evil were less tangible. The system of regulation of prostitution had been employed for years in European countries. The essential of this scheme was the registration of the women and their periodical examination. The object was to hygienize an unsalubrious occupation. Many statistics could be adduced to show that the regulation of prostitution diminished the spread of contagion. The difficulty of carrying out the system was that the women did not like to be registered as prostitutes, they did not submit willingly to medical examination, and had a horror of being kept in hospitals; hence many had been led to clandestine prostitution. This had made the occupation less susceptible of public control, and infinitely more dangerous to public health. It had always seemed to him a rank inequality of justice to submit the female offender to surveillance and allow the equally guilty male offender to go free. The most violent opposition to this system of regulation of prostitution had come from religious sects, who looked upon this licensing of such an occupation as putting a premium on debauchery. In this city the crusades against vice had too often been mere campaigns of force. Too often this had been the means of changing the *locale* and directing the business into new channels, but without diminishing the volume of this evil business. The arm of the law should be invoked in suppressing low dance halls, in raising the age of consent to twenty-one years, and in meting out the severest punishment to the men and women who made a business of selling human beings into something worse than slavery. Public opinion, which often had a force independent of its merits, forbade the establishment in this country of the continental system of restriction. It had been tried in St. Louis for about one year, but had then been swept from the statute books by an avalanche of protests, principally from women and the clergy. Incredible as it might seem, there was not now in this great city of ours hospital accommodation for more than one in two thousand of the prostitutes, there being only twenty-six beds for women afflicted with venereal disease, and all these were in the City Hospital. The men fared somewhat better, about fifty to sixty beds being provided. Appropriate treatment constituted the best form of prophylaxis. The feature of forcible detention was obnoxious, and it had been shown that more could be subjected to treatment by the voluntary system. The great point was to remove the ban against this class of patients. The plea made by many hospitals that venereal diseases were excluded because they were contagious was a mere pretext. Every hospital receiving municipal assistance should be compelled to open its doors to these people. A large proportion of syphilitics were ambulatory cases, and should be treated at the private offices of physicians or at dispensaries. The latter should be located in convenient parts of the city, and night classes established. These services should be conducted with all the privacy possible, and the cardinal principle be kept in mind that every case was a focus for the dissemination of the disease. The now obsolete practice of destroying the venereal sores by cauterization or by excision should, in his opinion, be revived. A good deal could be accomplished in the way of prophylaxis by a properly conducted campaign of education. In public practice it was impracticable to give such instruction, except by handing each syphilitic patient a printed pamphlet, stating in plain language the salient points regarding the spread of the disease, its dangers, and the advantages of prompt and persistent treatment. A theoretical and practical knowledge of venereal diseases should be made a requisite for receiving a license to practise medicine. The opinion of all medical men entitled to respect was that sexual continence was not incompatible with the best of health. There was no reason why young men should not be forewarned of the dangers and pitfalls for them. We must look to a higher order of education and *morale* among men as the best means of diminishing prostitution. The vast majority of fallen women became so, not from choice, but because of hard social lines that forced them into this life. Society should deal with them as unfortunates rather than as criminals.

Alcoholism More Dangerous than Venery.—Dr. Frederic R. Sturgis said that this subject had been thrashed out over and over again by medical men, but they had never arrived at any other conclusion than that prostitution should be restricted. He had been informed that insurance companies were studying with much interest the question as to how far venereal disease cut short human life, but so far no unanimity of opinion had been secured. If syphilis were the fatal disease it was supposed to be, he would like to ask what proportion of the population of towns and cities would be alive. Certainly a very small one. Public women had assured him repeatedly that, if they could leave the bottle alone, they would get along very well and might eventually become members of respectable society. The same was true of the men. In armies in which alcoholism was restricted there had been a very small proportion of physical wrecks. The figures on this subject that had been quoted were misleading, in that syphilis and gonorrhœa had not been considered separately. He was not one of those who attributed such a vast amount of morbidity and misery to gonorrhœa as some were inclined to do. Comparatively few syphilitics suffered from nervous syphilis, and he certainly did not believe that rickets was commonly the result of syphilis *per se*. A man might have syphilis for years, but he was not a source of contagion all that time. As a rule, the first twelve months finished the period in which one was liable to convey the disease by glass, pipe, or kiss. All the Anglo-Saxon races positively refused to traffic in vice.

Regulation Backed by Proper Public Sentiment the True Remedy.—If it were proper to regulate smallpox, the speaker asked, why not regulate the other pox? Attempts had been made not only in St. Louis but in Nashville and Louisville. In the last place it had failed because public sentiment had been so strongly against it that it degenerated into a farce. The speaker protested against the suggestion that the treatment of these people should be free; it was not done abroad—indeed, out of the small fees paid for such treatment an elegant hospital had eventually been built for them. Above all, they should not be allowed to come and go as they pleased. The physician who mixed medicines with morals was sure to come to grief; his true function was to show the people where the dangers lay.

Dr. Charles W. Allen said that ten years ago he had read in this academy a paper on the prophylaxis of syphilis. Among other things he had then suggested that the subject of syphilis be made so much more public that the general reader might be instructed a little more and understand what family syphilis meant to the community. The early recognition and prompt treatment of the extragenital chancres would accom-

plish much in the way of prophylaxis. Dr. Allen said that in the Good Samaritan Dispensary about 27,000 patients had been treated in 1887, and out of this number 386, or 1.25 per cent,, were venereal. Last year, 86,000 cases had been treated at this dispensary, of which about 5,000, or 5.7 per cent., were venereal. This would seem to indicate that venereal diseases were on the increase in that section of the city. Dr. Sturgis seemed to have left out of consideration altogether the enormous mortality among infants, arising from syphilis. It was all very well to talk about personal liberty, but it seemed to him well to have some means of controlling these people who would go out from the hospitals while in the infectious stage of the disease. The speaker urged the discarding of the term syphilis and substituting, as a less objectionable one, the word "lues." He was glad to see that this suggestion had been favorably received, and that the term lues was being more and more used in literature. It was common for even liberally educated people to be completely ignorant of the innocent modes of transmission of syphilis.

Stifle False Modesty and Educate the Public.—Mr. W. H. Baldwin, Jr., chairman of the committee of fifteen, was invited to participate in this discussion. He said that the remarks of the previous speakers had shown him a lack of unanimity among physicians on this subject, and, this being the case, what could be expected of others with less opportunity for information? He had been impressed with the earnest desire of many citizens for greater enlightenment on this important topic. Society should come in and protect the poor from contamination, so that their children would have an opportunity to grow up properly. In the course of the work of his committee, the subject of prostitution had received considerable attention and study by some of the members. They had studied the reports of the great conference in Brussels one year ago. The general opinion there seemed to be that regulation or licensing was impracticable, inexpedient, and impossible, because of the tendency to increase clandestine prostitution.

Segregation would Bring Relief.—This was not a subject to be quiet about; we should go about it in a healthy-minded way and face the facts, and explain the subject properly to the public. It was admitted that this evil could not be banished; if, therefore, it must be with us, it was our duty to see that it should exist in proper places, and that it should not exist where decency desired to reign. This business of prostitution must, by a process of elimination, tend to particular localities. One of our great preachers had protested against such a plan on the ground that it would be establishing a "little hell," but he, for one, would rather see a little hell so established than a very large hell.

A Voice from the "Red-Light District."—Mr. James B. Reynolds, head worker in the University Settlement, also took part in the discussion. He said that he had received the impression this evening that while physicians might differ as to the dangers of venereal diseases, they were agreed as to the importance of this subject, and the need for further investigation. He happened to live in that part of the city known as "the red-light district." In certain respects the scheme of regulation was applied more successfully in New York City than in Paris. The medical inspection of prostitutes was voluntary, but they were registered, as in Paris, and undoubtedly the taxing of these people was more systematically carried out, and the taxes were heavier than in Paris, yet no doubt the money was put to a different use. He was perfectly confident that the number of public women not known to the police in this district was very limited; they were known by the police and visited regularly. There were many at the present day who believed that it was not a good plan to attempt to remedy social evils by legislation; that it woud be better to let these evils regulate themselves spontaneously. He entirely agreed with Mr. Baldwin that the first and most important step forward must be with the medical profession, who must educate the people, and so shape public opinion that the efforts of laymen in the same direction would be accepted and appreciated. He was firmly of the opinion that the advertising features of this business should be destroyed.

On motion of Dr. S. A. Knopf, the president was empowered to appoint a committee of seven to ten persons to study this subject, with the object of securing municipal or State legislation for the restriction of prostitution.

Therapeutic Hints.

Varicose Ulcers.—

℞ Powdered iodoform,
Powdered salol,
Subnitrate of bismuth,
Powdered charcoal,
Powdered cinchona,
Powdered benzoin ..... āā p.æ.
M. To be used as a dusting-powder.

—Schwarz.

Falling of Eyelashes.—

℞ Acid. gallic ..... gr. viij.
Ol. ricini ..... ʒ ss.
Ol. lavandulæ ..... gtt. iv.
Petrolati ..... ʒ v.

Vomiting in Phthisis.—

℞ Menthol 1
Spir. vini gal. 20
Syrupi simpl 30
M. S. Dessertspoonful in water every hour.

Delirium Tremens.—Hyoscine hydrobromate gr. $\frac{1}{100}$ to gr. $\frac{1}{50}$ hypodermically.

Chronic Eczema and Psoriasis.—

℞ Creolin ..... ʒ ss.
Hydrarg. ammon ..... gr. x.
Petrolati ..... ʒ i.

—David Walsh.

Whooping-Cough.—

℞ Antipyrin ..... gr. ij.
Ext. bellad. fol ..... gr. $\frac{1}{20}$
Zinci oxidi ..... gr. ss.
Ext. castaneæ fl ..... ♏ i.
To each dose.

Ascites.—

℞ Ext. pilocarpi fld ..... gtt. xx.
Ext. cocæ fld ..... ʒ ss.
M. S. For each dose, thrice daily.

—J. N. Crabb.

Bedsores.—

℞ Zinci sulphatis ..... gr. xlv.
Plumbi acetat ..... ʒ ss.
Tinct. myrrhæ ..... ♏ xx.
Petrolati ..... q.s. ad ℥ ij.
S. Spread and apply.

Neuralgia.—

℞ Ext. hyoscyami ..... 0.12 gm.
Ext. valeriani ..... 0.20 "
Morph. hydrochl ..... 0.01 "
Pulv. glycyrrhizæ ..... q.s.
M. ft. pil. No. i. S. One such morning and night, or not over three in twenty-four hours.

Influenza.—℞ Ext. gelsemii fld. gtt. ii., repeated every half-hour until physiological effects are produced.—*Massachusetts Medical Journal.*

Cure d'Air is superior to other methods for mitral stenosis pure and simple. Dyspnœa, pneumonia, and

bronchitis are avoided, as is the tendency to tuberculosis. The supply of fresh air must be permanent, day and night.—SURMONT.

Sciatica.—

℞ Ol. terebinth.,
Acid. acetici ..... āā ʒ vi.
Camphoræ ..... ʒ ij.
M. S. Apply.

—*The Med. Times and Hosp. Gaz.*, March 17, 1900.

Fatty Heart.—

℞ Sodii arsenatis ..... gr. $\frac{1}{24}$
Potass. iod ..... gr. $\frac{3}{4}$
Pulv. nucis vom ..... gr. $\frac{1}{2}$
Pulv. rhei ..... gr. $\frac{3}{4}$
Ext. dulcamaræ ..... gr. iss.
M. ft. pil. No. i. To be taken daily.

—A. ROBIN.

Bleeding and Tender Gums.—

℞ Gelatin ..... ʒ ss.
Sodii chlorid ..... gr. viij.
Acid. carbol ..... gr. ij.
Eucain β hydrochl ..... gr. viij.
Cocain. hydrochl ..... gr. ij.
Aquæ destil ..... ʒ iiiss.
M. S. Use as mouth wash.

Furuncle.—

℞ Hydrarg. oxid. rub 1
Lanolin 10
M. S. Apply thoroughly once daily.

—JORISSENE.

Asthma.—

℞ Argenti nitratis ..... 0.10 cgm.
Ext. belladonnæ ..... 0.20–0.30 "
Ext. menyanth ..... q.s.
M. ft. pil. No. xxx. Two or three daily after meals.

—GOULOUBOR.

Palmar Syphilides.—

℞ Acid. salicylic ..... 1.20 gm.
Ichthyol ..... 2. "
Ung. aq. ros ..... 30. "
Apply each night and wear gloves.

After the above has cured the lesions, apply the following to ward off recurrences:

℞ Calomel ..... 1 gm.
Ung. aq. rosæ ..... 30 "

—OHMANN-DUMESNIL.

Antispasmodic Injection.—

℞ Valerian root ..... 30 gm.
Infuse in:
Boiling water ..... 250 "
Filter and add:
Asafœtida ..... 4 "
Yellow of egg ..... No. i.
S. For rectal use.

Antineuralgic Pill.—

℞ Zinci valerianat ..... 0.05 cgm.
Quininæ valerianat ..... 0.10 "
Ext. opii ..... 0.01 "
Ext. bellad ..... 0.05 "
For one pill. S. Two to six daily.

—YVON.

Sweating in Phthisis.—

℞ Scopoliæ (alkaloid) ..... 0.015 mgm.
Spt. vini rect ..... 6. gm.
M. S. Gtt. x. three times daily.

—DUCKWORT AND DUNSTANT.

Puerperal Peritonitis.—I observed that when I could salivate them they got well.—G. C. E. WEBER.

In Variola salol abolishes all sense of irritation and desire to scratch. Maturation is usually prevented. Dose, fifteen grains three times a day.—CHARLES BEGG.

Antitetanic Serum.—Twenty c.c. on the second day, 40 c.c. on the third, 30 c.c. on the fourth, and 10 c.c. on the fifth brought about uninterrupted recovery, in a boy injured by a toy pistol.—E. B. ADAMS.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 2, 1901:

	Cases.	Deaths.
Tuberculosis	267	161
Typhoid fever	23	11
Scarlet fever	541	30
Measles	167	8
Diphtheria and croup	293	36
Smallpox	64	11
Typhus fever	1	0
Varicella	79	0

In Severe Anæmia arsenic is usually suitable, especially if there is reason to believe that pernicious anæmia is at the root of the symptoms. In curable lymphatic anæmia arsenic is inferior to iron.—HAYEM.

Health Reports.—The following cases of smallpox, yellow fever, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 2, 1901:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.			
Alabama, Mobile	February 16th to 23d	..	1
California, Los Angeles	February 9th to 16th	1

THE TREATMENT OF GONORRHŒA WITH FREQUENT IRRIGATIONS OF HOT DECINORMAL SALT SOLUTION.

BY CHARLES E. WOODRUFF, M.D.,

UNITED STATES ARMY, FORT RILEY, KANSAS.

THE positive knowledge gained in the last two decades of the disasters and deaths due to gonorrhœa and the great length of time during which the gonococcus can remain quiescent in the tissues, has resulted in a feverish search for remedies and methods of quick, sure cure. An outsider, calmly considering the drugs and methods advocated, is rather bewildered at their multiplicity, and from the way the profession stampedes to each new thing proposed he acquires the impression that nothing yet has been satisfactory—an impression rather intensified by the fact that new reliable text-books advocate methods differing in no essential from those used for half a century.

The discovery of the highly germicidal properties of silver nitrate for the gonococcus and the progressive production of other silver salts less irritating to the urethra, argentamin, argonin, protargol and largin, seem to have lessened the duration of treatment and, in the hands of some surgeons, apparently leave little to be desired. It is even reported that a few bougies of protargol night and morning, followed by an astringent injection for a few days longer, result in a permanent cure in most cases, and in nearly all of the early cases; and that the injection of a few drops of a twenty-per-cent. solution of protargol in glycerin into the fossa navicularis, after a suspicious intercourse, will surely destroy all the gonococci which may have been received—that is, the earlier the treatment with the new germicides the more surely can we abort the disease.

Jules Janet and Valentine, by popularizing the method of irrigations, have also just as surely revolutionized our ideas as to the time of cure.

Yet it is said that a large number of alleged rapid cures are not cures at all, but that the infection still exists latent, and that relapses are liable to occur for weeks or months and occasionally for years. Within a year or two, prominent specialists have stated that the patients are not now cured sooner than they were formerly, that the aborted cases are a mistake, and that modern treatment may weaken the virulence and reproductive power of the gonococcus more often than it destroys the gonococcus itself, an attenuated germ remaining in the tissues ready to take on virulent growth at a favorable opportunity, or when planted in a new host. With most surgeons, indeed, freedom from complications is still considered of far more importance than short duration of treatment, and one often gathers the impression that active efforts to abort the disease or cure it quickly are too dangerous, an occasional writer even advocating leaving all cases alone, except for their hygienic management.

Professor Gross, as late as 1886, taught his students that the patient who recovered in seven weeks was supremely fortunate, but now, from the general tenor of the papers, we are chagrined if the average case is not well in three weeks. The new "International Text-Book of Surgery" states that cases still last three to seven weeks, but Keyes and Chetwood state that two weeks must be considered short, three weeks reasonable, and four weeks not excessive. The latter-day view is certainly not borne out by the statistics presented by Vogl,[1] reviewing the treatment in the military hospitals of Munich since 1882. Before this time the treatment averaged forty-five days. In 1893 the use of silver salts was begun, but the treatment still averaged forty-five to forty-seven days; after 1896 the average was forty days, but some cases were discharged not cured. In 1896 treatment by silver nitrate, permanganate, and protargol averaged forty-two days, and some cases were not cured. It thus seems that, in Germany, specific remedies had failed, and that there was no treatment any better than the old plan of hygienic management—rest, plain diet, rendering the urine bland, and applying cold in the acute stage.

In looking over the germicides added to the water in the modern irrigation treatment and considering their strength, one is justified in being sceptical also as to the value of specifics used in this way, and in suggesting that plain water would do as well. The germ, though at first a resident of the upper layers of the mucous membrane, extends deeper and is entirely out of the reach of any germicide; and though these weak solutions might kill the germs on the surface, we do not need to kill them if we are to wash them out, and plain water will sweep them out just as well as a weak germicide. In my own experience with Halsted's method it did not seem to make any difference whether corrosive sublimate were added or not—the patients recovered as soon one way as the other.

The excellent results of weak permanganate of potassium irrigations give the same impression, and Dr. Guiard,[2] in discussing Dr. Motz's methods with this drug, has claimed that just as good results are obtained with weak solutions, 1:5,000 or 1:10,000, and, moreover, that they never produce the pain, hæmaturia, or serious reaction of the stronger solutions. Now, surely so weak a solution of permanganate can have little germicidal power for the short time it is in the urethra, and might just as well be omitted. In some of my own cases there was so much complaint of the pain that the drug was omitted; and the patients seemed to progress to recovery more rapidly on plain water. It is, then, justifiable to doubt the efficacy of any germicide in irrigation, and to assume that the good results are due to washing away the germs and toxins, leaving the tissues to destroy the rest. K. Josse[3] claims that irrigations are beneficial, by reason of the gentle massage they produce, and he gives this as one reason for his own method of treatment by massage.

The gonococcus is such a frail exotic, so difficult to keep alive in artificial media, that it was long believed

[1] Münch. med. Woch., August 1, 1899; see Med. News, November 25, 1899.

[3] Centralblatt f. Harn- u. Sexual-Organe, Leipsic, June 16, 1900.

to be a pure parasite, incapable of growth outside of the host. Almost anything can be expected to kill it —chilling, drying, etc.—and we know that the disease is rarely transmitted except by direct transfer from host to host, and that if it is transmitted by mediate transfer, it is done shortly after the germs have left the preceding host, the medium introducing the fresh, moist germs, as by moist towels, basins, etc. It is perhaps unknown for the dried, chilled germ to infect. The lower thermal death point is not known, but the germ will not grow if kept colder than 79° F. Its range is said to be 86° to 94°, and above 100.4° it will not grow at all. Every degree beyond the growing limits must weaken the gonococcus, even if the effect is not fatal. I have known soldiers with gonorrhœa, taken down with high fever from some other infection, to have the discharge cease entirely, only to return upon recovery from the second infection, the gonococcus remaining "attenuated" in the interval of high temperature. Neisser demonstrates that 113° F. destroyed the virulence and reproductive power of the germ, though we must presume that it must take some time to do this, for Sternberg shows that 140° F. is fatal in ten minutes. Here, then, is a method of treatment better than germicides, for we can surely warm the deep gonococcus to a temperature of 113° F. by copious irrigations. According to the MEDICAL RECORD, Callori[1] reports that his treatment with water of this temperature is successful in most instances. He advises a preliminary injection of cocaine. Perhaps if he had repeated the treatment at shorter intervals, he would have been still more successful. Even the old empirical treatment of bathing the penis frequently in water as hot as could be borne, must have inhibited the gonococci, and to do this from the inside is far more rational. Though we cannot reach the high degree of heat necessary to kill the gonococcus quickly, yet we can keep up lower degrees indefinitely, by increased frequency of irrigations. As soon as the germs are thus attenuated, the tissues can be depended upon to destroy them, if we only see to it that the tissues are not damaged or their powers destroyed, and that the patient's general nutrition is improved.

Indeed, heat is an essential of the treatment with many surgeons, though the results are not reported as due to the heat. Dr. Menachem Hodara,[2] of Constantinople, reports that his cases last two to four weeks under his method of hot irrigations with nitrate of silver, beginning with 1 : 4,000 and gradually strengthening to 1 : 2,000, using a pint at a time. Perhaps Valentine's brilliant results are in part due to the heat of the fluids used, and surely the good results of baking gonorrhœal joints in arthritis must be due to the germicidal power of the heat.

Plain water is irritating to all mucous and serous membranes, and distilled water exceedingly so, for by the laws of osmosis, it soaks into the epithelial and endothelial cells, swells them, causes their detachment, inducing catarrhal denudations and increasing catarrhal discharges. The use of salt solution of normal strength is a matter of daily routine, yet it is rarely mentioned in regard to the urethra, where plain water must be just as irritating as we know it to be elsewhere. One of my own patients complained so bitterly of the pain from a germicide, that a hot decinormal salt solution was used to soothe the membrane, and, much to our surprise, the discharge and other symptoms ceased at once; for I had been irritating the inflamed membrane instead of soothing it. Since then I have stuck to the salt solution for all cases. It is really illogical to take so much trouble to render the urine bland and unirritating, and then to spoil the effect with irritating drugs, which can only damage the natural resisting-powers. Patients not infrequently recover as soon as irritating injections are stopped.

These observations suggest the thought that perhaps most irrigations succeed because they wash out the poisons, and not by reason of the germicides, but in spite of them. An infected spreading chancroid will heal quickly if it is washed often enough. In a persistent case of this kind, many years ago, in an eastern hospital, the patient was experimented upon with all kinds of caustics by every one in turn for a year or more, until but little was left of his penis. Finally, a bright interne applied an old treatment and kept the patient seated in a bathtub of warm water from morning till night, day after day. The ulcer thus constantly washed, got well at once. I have used copious and frequent irrigations upon soldiers for several years, sometimes cauterizing the ulcers first. It does not seem to make any difference what cautery or germicide is used, or whether any—the irrigated ulcers seem to get well as soon as any other granulating wound which is assisted, and not damaged, by our efforts. The constant bath is now the standard treatment in skin infections of severe type.

In gonorrhœa, then, it is a simple matter to cleanse with a fluid as hot and unirritating as possible, and as often as possible. Being at first only a local disease, only local treatment is needed. There are no nauseating drugs to damage the stomach, no annoying chemicals, no restrictions in diet except as to the articles we know to be irritating, nor confinement to bed, nor is there necessity for alkalinizing the urine, but only for diluting it when it is too concentrated. Instead of using a weakening and depressing treatment, we should build up the strength so that the powers of resistance are increased to the point where the tissues can dispose of the germs, which they eventually do in every case. Increased resistance from good nutrition is just as important as in other gonorrhœal infections. Reduction of diet is as bad as venesection.

The latest studies of the gonococcus[1] show that the gonotoxin, excreted by the coccus, is exceedingly poisonous in small quantities, and it is a logical treatment to wash it out of the urethra as often as possible. Therefore, the irrigations should be given at least every hour, though excellent results will follow from two or three hour intervals. Indeed, Col. John Van R. Hoff, U. S. A., informs me that he has secured excellent results from one irrigation daily, of very hot water, kept up about seven days; but he kept up the irrigations continuously for a whole hour every day. In the case of soldiers it is best to keep them busy and out of mischief, and constant treatment is more practicable.

Omitting the cases which were chronic or had complications when admitted, the cases apparently cured remained in hospital as follows:

Number of Cases.	Days in Hospital.	Number of Cases.	Days in Hospital

Thus, about 30 per cent. last 7 days; 30 per cent. 11 days; 20 per cent. 17 days; 10 per cent. 20 days, and 10 per cent. over three weeks, though the actual duration of the symptoms is less than this, as each case is retained in hospital two or more days after all symptoms have disappeared. In a small number, about 5 per cent., all symptoms disappear within 2 days; in another number, say 10 per cent., within 3 or 4 days, and, as a rule, there is a marked reduction within a week, and a total cessation in 10 to 14 days. This does not mean that the cases are well by any means; for the biology of the gonococcus would lead us to believe that attenuated ones may be present for a long time, ready to take on virulent growth upon any indiscretion in habits. This early cessation of discharge is really a danger in any treatment, but it may be overcome by carefully explaining the conditions to every man. My own practice is to give each soldier an astringent injection to use for two or three weeks after he leaves the hospital, and the few who return with the disease lighted up again generally have a story of drinking, or of failure to do as directed. I have no means of telling how many relapse, though after careful inquiry I believe the number to be very small—in the above ninety-eight cases there were not more than six or eight. When it is remembered that, as soon as soldiers are sent out of hospital, they must take part in active gymnastic drills and exercises, including horseback riding, and that they are prone to drink beer, the small number of relapses is very gratifying. It is equally gratifying the way chronic uncomplicated cases will promptly improve under hot irrigations; some patients even in a few days, though they had suffered for two months or more before entering the hospital. Confinement to hospital on a plain diet, and avoidance of all exercise, no doubt, are very efficacious of themselves and may make the treatment look better than it really is. Early cases in which but a short length of the anterior urethra is supposed to be infected, may be actually aborted, and about as often as by other methods. As a preventive after a suspicious intercourse it has not been tried, but it is likely to be found just as efficacious as the irrigations with hot, weak permanganate are said to be.

If a discharge keeps up more than ten days, I usually find that the irrigations are not properly done. Sometimes there is not enough pressure to fill the urethra and wash out its folds, though a pressure of more than four feet is excessive and quite apt to cause complications. Sometimes the patient constricts the penis so that the water does not go in farther than an inch or two. He must be taught to wash off the glans, then the meatus, then more and more of the urethra until it is all ballooned out. There is in this way little or no danger of forcing the poison any farther back than it usually goes in every case by simply spreading along the folds. Sometimes the meatus is too small and must be enlarged, and old strictures will of course prevent irrigations and must be first remedied.

Though all of the patients were apparently cured, we might consider the ten per cent. of cases lasting more than three weeks as practical failures. Yet some of them were due to carelessness, and there were also cases complicated with more or less destruction of tissue requiring time to repair the damage—cases, by the way, needing cleanliness just as much as the others.

Specialists are almost unanimous in condemning the practice of placing irrigations or injections in the hands of the patient in the acute stage, yet I have seen no harm come from the patient's simply washing out the penis with a quart of hot salt solution every hour, provided he is properly instructed. The complications, such as orchitis and peri-urethral inflammations, are nearly all due to saddle injuries at drill.

I have tried other methods of internal medication, including salol, and the mixture of methylene blue and the oil of cinnamon or nutmeg, and santol, but it is not at all certain that there was any difference between these cases and those simply irrigated. Internal medication is not of much avail. Bougies of protargol at night seem to be good, but I have had to stop them, as they irritated and seemed to be doing more harm than good. A simple treatment without drugs is of great practical value in this as in all other diseases of military life, for active service is apt to be in far-off places where it is impossible to get all the complicated apparatus considered essential in civil practice.

We do not see all the cases of gonorrhœa among soldiers by any means, as there is a natural desire to hide the disease. Yet they do not contract it in any greater numbers than do the same class of men in civil life; indeed, it is quite likely that there are fewer cases among them, on account of their higher average of strength and, therefore, greater resistance to any infection. Nearly all of them being normal men, they have the advantage also of that undoubted personal equation which exists in relation to the normal man's resistance to the gonococcus as a result of natural selection. As with all other parasitic bacteria, this one, no doubt, arose from harmless saprophytic ancestors, by the survival of those having variations permitting of a parasitic existence. It must have taken many thousands of years for this to occur; for we cannot make new breeds of bacteria in the laboratory. We can modify or attenuate them; but as soon as their normal environment is restored, they revert to ancestral types. The gonococcus and man probably underwent evolution together, and there must have been a greater survival of those men in whom, by natural variation, there was more or less resistance, the more susceptible having been killed off. My own investigation among some California Indians leaves no doubt in my mind that the gonococcus was not in that part of America prior to the arrival of whites. There had been no weeding out of susceptibles, and when the disease was introduced its ravages were terrible.

White men occasionally revert to ancestral types and show no resistance. They have bad cases, and seem to be easily infected when other men escape. It is a matter of observation among soldiers that there is something essentially peculiar about the men who do not recover soon under any treatment. They are often devoid of that normal natural *savoir faire* of most men, impractical, often stupid and filthy. They are evidently abnormal and perhaps atavistic in their lack of immunity. As a rule, normal men recover sooner than the abnormal, though they may receive severe infections, and very abnormal men sometimes escape. Yet it is quite likely that the failures in any method of treatment are mostly in degenerates with well-marked stigmata, and that they would be equally hard to treat under any other method. Degenerates, by the way, are far more liable than the normal to excesses of alcohol and venery, and also more liable to gout, rheumatism, rickets, tuberculosis, and other infections, all of which destroy immunity to gonorrhœal infection, or increase the virulence. The above-mentioned work by Christmas also shows that there is an antitoxin formed in the blood of animals injected with gonotoxin. Perhaps this also occurs in man, and in normal and robust men, quite likely it is formed better than in the weak or abnormal. The proved inefficiency of many methods of treatment under which patients recover in time, rather strengthens the suspicion that the antitoxin is always formed, and that the disease is really self-limited, like typhoid, and has a period between forty and sixty days, and that the patients recover naturally in spite of the treatment, not by reason of it. Chronic and severe cases, then, are in the abnormal, or in those of bad habits, or when there

is much destruction of tissue or its vitality is reduced by bad treatment. Some surgeons even depend upon tissue resistance, until the case becomes chronic.

There is no use in trying the above treatment unless one is sure that the patient is properly instructed, and really does wash out the urethra, and not the mere end for an inch or two. Soldiers are exceedingly ingenious in doing it the wrong way and delaying recovery. I find a simple, short glass tube is a good enough nozzle, and each patient should have one, which he should sterilize after use, at the same time he sterilizes his hands, solutions being kept on hand for the purpose.

A WHISTLE IN THE ŒSOPHAGUS.

By A. E. ISAACS, M.D.,

NEW YORK.

In the Medical Record of October 27th, Dr. G. W. King, of Helena, Mont., reports a case of a foreign body impacted in the œsophagus of a child, and its presence there revealed by the aid of the *x*-ray. I have had a case so similar in all regards that as I received the copy of the radiograph and read the history of the case I was struck with the remarkable similarity between the two. The description of Dr. King's case, up to the treatment by œsophagotomy, would exactly apply to my patient, except that he was a boy aged four years, and that no anæsthetic was used in the attempt to locate or remove the whistle. He was more fortunate as to the success of the milder methods of treatment, and I believe the success was due to the special instrument employed, on account of which I believe this case worthy of record.

The boy first came to me two days after having swallowed the whistle. Although the symptoms had been urgent at first, by this time they had so much

Fig. 1.—Radiograph of Whistle.

improved that what remained could very well be accounted for by the irritation from previous attempts to locate or dislodge the impaction. He had been to a number of physicians and no one of them could say whether the whistle was in his throat or not, with one exception (which, for reasons of his own, the father did not tell me of till after I had extracted the whistle), and that was at one of our largest hospitals. They discovered it with the aid of the *x*-ray, and failing to remove it by the ordinary means proposed an œsophagotomy, which the father refused.

As far as my finger could reach, I could not feel any foreign body. Œsophageal forceps of different kinds, which if they had touched the foreign body would certainly have indicated that fact, were passed without locating anything. Subsequent developments proved that they passed beyond the whistle without touching it. An œsophageal bougie and a bristle probang were used without any result. With the idea that the whistle, if any at all had been swallowed, had most probably already passed to the stomach, I put him on the table for an *x*-ray photo, and told him to

Fig. 2.—Hinged Bucket.

call the next day for the result. To my surprise the radiograph showed that the whistle was lodged in the œsophagus.

Before the patient returned I hunted up various forceps and devices for the removal of foreign bodies from the throat. Among others I got what is called a "coin catcher" or a "hinged bucket," and tried this first, as I had already learned by experience that the different forceps did not even touch the body. I passed the "coin catcher," and, pulling it up, out came the whistle on the first attempt.

In view of the fact that Dr. King's case had to be operated upon, and the fact that my patient was advised to submit to operation after failure of other means tried at one of our principal hospitals, I consider myself fortunate in having procured that very ingenious contrivance, the "hinged bucket," that so easily and efficiently did the work. It is an old-time instrument that seems to have fallen into disuse, but considering the frequency of foreign bodies lodging in the throats of children especially, it should have a place alongside the throat forceps and bristle probang in every physician's instrument case. The accompanying illustrations are a copy of the radiograph taken at the time and an illustration of the "hinged bucket."

240 East Broadway.

THE TREATMENT OF COLITIS BY VALVULAR COLOSTOMY AND IRRIGATION.

By P. R. BOLTON, M.D.,

NEW YORK,

SURGEON NEW YORK HOSPITAL.

The treatment of some forms of colitis by diverting the fecal current and sparing the mucous membrane of this part of the intestine from contact with it by establishing an artificial anus in the cæcum, which should also facilitate topical applications to the mucous membrane, is not of recent origin;[1] and this plan has been carried out with gratifying results in a number of published cases. Nevertheless, it has not been much utilized, for, aside from the fact that many cases of ulcerative and other kinds of colitis get well through the use of simpler measures, the presence of an artificial anus with its inevitable discomfort which patients are compelled to endure for periods which it is impossible to foretell, and the positive risks entailed in attempts at closure of such a fistula, have made it difficult to recommend this plan of treatment.

The fact that many cases of ulcerative colitis or proctitis end in recovery under the influence of irrigations made through the rectum without any diversion of the fecal stream, leads naturally to the belief that by so regulating the diet and digestion as to introduce into the colon fecal matter of at least approximately normal character, no obstacle to recovery of the mucous membrane exists in the passage through the colon of

[1] Keith: Lancet, March 7, 1895.

fæces *per se*. The capacity of the colon is said to be nine pints. It is a matter of every-day experience that it is exceedingly difficult to inject into the normal colon even a quart of 0.5-per-cent. salt solution without provoking a degree of tenesmus that makes its expulsion imperative; and this is the more true when the mucous membrane of the colon is inflamed and hypersensitive and the injected fluid one at all irritating. One cannot avoid the conclusion, therefore, that in even favorable cases but a portion of the mucous membrane of the colon can be reached by injections made through the anus, and that to insure contact of the medicating solution with the entire mucous membrane of the colon fluid must be forced through from the cæcum.

With these premises in mind the logical conclusion is that a simple fistula made in the cæcum would fulfil every indication; and of the various styles of fistula one which would admit of the ready introduction of fluids without the annoyance of continuous leakage, and which finally would close spontaneously without requiring any plastic procedure, would best fulfil the indications.

Dr. Charles L. Gibson, surgeon to St. Luke's Hospital, therefore proposed to me to apply to the cæcum the plan accredited to Kader, and found so successful in the performance of gastrostomy, as best suited to the purpose in view.

The result achieved in the simple case reported herewith justifies so far as it can the adoption of the principles of the treatment employed and the method used in the formation of the fistula.

The patient, male, aged forty-two years, was referred to me by Dr. Julius Frankel, of this city. His family history was negative. Eight weeks before his admission to the hospital, without assignable cause, he developed a severe diarrhœa accompanied by fever and prostration. The diarrhœa persisted in spite of all treatment; the evacuations occurred from sixteen to twenty-three times in twenty-four hours, were blood-stained, and contained a good deal of mucus. There was loss of strength and of thirty-one pounds in weight.

Examination showed a considerable emaciation and anæmia. The mucous membrane of the rectum and sigmoid flexure was congested and everywhere presented very numerous superficial ulcerations, varying from one-eighth to three-eighths inch in diameter. The urine was normal. The fæces contained much mucus, blood, and pus; but no amœbæ were found.

The first step in the treatment consisted in the formation of a cæcal colostomy as follows: A one-and-a-half-inch incision was carried through the abdominal wall parallel with the right Poupart's ligament and an inch internal to its outer part. The cæcum at once presented. A point was chosen in its anterior band and the intestine opened sufficiently to admit a fair-sized soft-rubber catheter. Three tiers of sutures placed above and below this orifice served to infold the cæcal wall. The ends of those last introduced, left long and carried through the margins of the abdominal incision, brought the cæcum forward into close contact with the abdominal wall and further were utilized to close the external wound, being reinforced by a silkworm-gut suture at each angle. Healing of the abdominal wound was without incident.

The after-treatment consumed about four weeks, but the patient was confined to bed for the first half of this time only. He was put upon a diet at first composed entirely of proteids and took salol and castor oil in small doses every three hours, but toward the close of his stay in the hospital a mixed diet was allowed.

Irrigation of the colon was begun at once. The patient was placed on an ordinary douche pan and a large Kelly urethral speculum was passed through the anus and then several quarts of 0.01-per-cent. solution of silver nitrate were injected through the catheter, and the colon was thoroughly washed out. The silver solution was then followed by 0.5-per-cent. salt solution. For the first three days this washing was done twice daily; for the next eleven days once daily and the strength of the silver solution increased to 0.02 per cent.; for the remaining time every other day.

After the seventh day the catheter was removed except at the periods of washing, and in the intervals there was absolutely no leakage. Even during the injection when the cæcum and ascending colon were tightly distended and bulging the abdominal wall, no fluid followed if the catheter was withdrawn.

There was never any difficulty in introducing the catheter. From the first the diarrhœa began to improve; at the end of two weeks no ulceration of the mucous membrane could be seen, and at the time of the patient's discharge from the hospital the mucous membrane of the rectum and sigmoid seemed normal; he was defecating without pain from one to three times daily; the stools contained nothing abnormal; his weight had increased ten pounds.

After leaving the hospital a small pad was worn for twelve days, at the end of which time the track of the fistula was entirely healed. Since discharge the patient has been well, and has continued to gain flesh and strength.

A small ventral hernia has appeared at the site of operation, which, I think, can easily be controlled by a pad or closed by operation. In future I shall adopt the intermuscular incision of the abdominal wall, although this plan may possibly render the preservation of the patency of the fistula difficult, particularly if the treatment has to be extended over a considerable period.

48 West Forty-ninth Street.

THE OVARY; ITS RELATION TO NORMAL FUNCTIONS AND TO PATHOLOGICAL STATES.

By SAMUEL W. BANDLER, M.D.,
NEW YORK.

Ovulation.—One of the functions of the normal ovary is the production and expulsion of ova capable of being fecundated. It is probable that after birth no new ova are formed from the germinal epithelium. At and after puberty we judge the vitality of the ovary by its ability to bring these ova to a stage which may be called ripe. For the expulsion of an ovum from the Graafian follicle, a gradual increase in size of the follicle takes place, depending partly on an increase in the amount of liquor folliculi. The cells of the follicle epithelium undergo fatty degeneration, and the internal layer, the tunica interna, shows an increase in the size of the cells, and a decided development of the blood-vessels. The protoplasm enlarges greatly, begins to take on a yellow color, and these cells, now lutein cells, are arranged in several layers, forming an irregular surface. As a result of the fatty degeneration of the follicle epithelium, the ovum is freed from the cumulus oöphorus. The most prominent point of the follicle is poor in blood supply, and furnishes the so-called stigma folliculi. It is here that the opening takes place which serves as an outlet for the ovum. This opening is probably the result of the reaction or chemical effect produced by the ripe ovum, since in the newly born, and in children, follicles of the same size and even larger ones exist without bursting—the so-called atresic follicles. The facts that large follicle cysts occur in the ovary without opening, and also that in women in whom the unopened follicles degenerate, disturbances of menstruation occur—so-called missed

ovulation—speak for a chemical reaction as probably one of the functions of the ripe ovum. That the orgasmus venereus does play a part in hastening the expulsion of the ovum is not to be questioned. In most cases the opened follicle is then filled with blood which likewise empties into the peritoneal cavity, and the so-called corpus luteum spurium results. If pregnancy takes place, this body develops decidedly, forming the corpus luteum verum (Nagel).

After ovulation, the ovum is thrown out into the abdominal cavity, and then, influenced by the wave movement of the ciliated epithelium of the tubes, the fimbriæ of the ampulla, and the fimbriæ ovaricæ, finds its way into the uterus. It is not necessary that the tube should grasp or surround the ovary, since it would embrace, even under favorable circumstances, only part of the ovary. This wave movement of the ciliated epithelium causes a current in the peritoneal plasma, which directs the ovum into one or the other of the tubes.

Lode injected, with a needle pointed toward the diaphragm, the eggs of ascarides into the abdominal cavity of rabbits, in the region of the umbilicus. After ten hours, without the excitement of coitus, he found these eggs in the tube. An interesting proof of the existence of this current is given by Knauer, who removed the ovaries of dogs, and sewed them into the mesentery. In one case, on opening the abdomen he saw in one of the ovaries three ripe Graafian follicles. Shortly after, coitus took place, and in due time two young were born. A further proof is found in the experiments of Leopold who showed that an ovum given off by one ovary may enter the tube of the other side. The cases are not rare in which the tube of one side was closed or absent, and although the corpus luteum verum was found in the ovary of the same side, yet the ovum was found in the uterus. The same is true of those cases in which the corpus luteum verum is on one side, and the ovum develops in the other tube, or in the horn of a uterus unicornis of the opposite side. Therefore it is certain that, normally, a wave current exists on either side of the uterus, and that the ovum is attracted by the stronger current, usually that of the side from which it came, possibly, however, by the current of the other side.

Lode has shown that an ovum finds its way through the tube into the uterus in thirty hours.

Menstruation.—Menstruation is the periodical loss of blood from the uterus or from any mucous membrane, and may be divided into three periods: the præmenstrual, the menstrual, and the postmenstrual. During the præmenstrual period, the ten days immediately preceding the appearance of blood, the following changes take place:

The superficial capillaries become greatly dilated, and serous infiltration of the endometrium takes place, which separates the meshes of the stroma, accompanied by a gradual but decided dilatation of all the blood-vessels and lymph channels. There occur a growth of round cells in the interglandular tissue, and an entrance of leucocytes into the mucous membrane. The glands become larger and wider, being often filled with secretion.

This swelling of the mucous membrane, the dilatation of the blood-vessels, the production of round cells, and the growth of the superficial layer of the endometrium produce the so-called decidua menstrualis. Although in the connective tissue large cells, not to be distinguished from young stages of decidua cells, are found, it is to be noted that typical decidua cells do not, as a rule, develop at this time in the superficial layer. The endometrium is at this period from 6 to 7 mm. in thickness.

The period during which blood is thrown out is the next, or menstrual, period. The superficial capillaries are greatly dilated, and an exit of blood elements, not dependent on a bursting of the capillaries, goes on for several days. The bleeding occurs partly through diapedesis, and, in strong bleedings, through rhexis. There is little or no destruction of the mucosa, only a very slight fatty degeneration of the epithelium of the uppermost layer, so that in the excreted blood relatively few epithelial cells are found.

After menstruation, the uterus shows an almost continuous covering of epithelium, interrupted in spots, especially if pathological processes be present. Most of the ciliated epithelium is preserved. The first stimulus to bleeding is due to contraction of the uterus, which at the height of congestion is possibly accompanied by contractions of the tube. During menstruation the uterus is larger, and in the first few days following likewise soft and flabby. The flabbiness lasts longer than the bleeding. A spontaneous dilatation of the cervix canal takes place, and reaches its height on the third or fourth day. This dilatation takes place without regard to the amount of blood discharged, whether the menstruation be painful or painless. The cervix is hyperæmic, the glands showing an increased secretion of mucus. The blood thrown off is mixed with the mucus of the uterus and cervix, and later with the acid secretion of the vagina, for this reason coagulating less easily than other blood.

The secretion from the sebaceous glands of the external genitalia is responsible for the peculiar odor present in some cases, and in nowise differs from that observed in the axilla. On the inverted uterus the blood has been observed to appear in single drops from the region of the openings of the glands. The endometrium is then covered with white and bloody mucus, the openings of the glands being clearly seen. There is no degeneration or destruction of the mucous membrane. The changes in the tubes, if any, are slight (Gusserow).

The next, or postmenstrual, period comprises fourteen days, during which the mucous membrane returns to a thickness of 3 mm. During this time all cells not capable of further growth are thrown off, and the epithelium, only partially denuded, is regenerated. The epithelial cells found singly or in groups in the lumen of the glands disappear by resorption, and partially by phagocytosis. From the sixth day after the beginning of menstruation, cell division is prominent. It is probable that mitosis takes place, even during the exudation of blood. The presence of mitosis in the leucocytes is an evidence of growth of the interstitial tissue during menstruation.

Regeneration concerns the stroma, the glands, and surface epithelium, reaching its height on the fourteenth or fifteenth day after the beginning of menstruation. The mucous membrane becomes pale, the glands and vessels have returned to their normal state, the lost epithelium has been restored. From the middle of the third week on there is a diminution in mitosis.

Menstruation is not a process by which the mucous lining of the uterus is thrown off, with subsequent regeneration previous to the next menstruation. It is simply the excretion of blood from the decidua menstrualis occurring for the simple and sole reason that there is in the uterus no fecundated ovum.

Ovarian secretion is the direct cause of this periodical swelling of the mucosa, and it continues, if fecundation has taken place, to exert, not alone a local, but likewise a stimulating influence on the general and sexual organs. This stimulation occurs to a heightened degree during pregnancy, and on removal of the uterus, since the secretion is ordinarily excreted during menstruation. On the occurrence of pregnancy, this secretion causes a further development of the uterus and the decidua, and plays an important part in the process

of labor; it stimulates the functions of the breasts, exerts a decided constitutional stimulation, and is the cause of many of the pathological conditions occurring before and during labor.

The generally accepted view as to the relation between ovulation and menstruation is that of Pflüger. The increase of the contents of the Graafian follicle, which results through the secreting activity of the cells of the membrana granulosa, is said to stimulate the nerves running in the stroma and ending in the cells. The increasing tension reflexly irritates the vasomotor centre, with resulting dilatation and congestion of the uterine vessels. At the height of this congestion the follicle is supposed to burst, through pressure. As congestion and tension in the ovary are supposedly the reflex causes of the congestion of the uterus and pelvic organs, menstrual bleeding is considered a result of periodical ovulation. This theory obtained support through the experiments of Strassman, who showed that increased tension in the ovaries of animals, produced by the injection into them of fluid, caused swelling of the mucous membrane of the uterus. In answer it may be asked why the same condition does not result in all cases of ovarian tumors and ovarian cysts, which may develop entirely beneath the albuginea.

This theory of Pflüger and the experiments of Strassman have been generally quoted to prove the causal relation of ovulation to menstruation. The congestion in the ovary, and the swelling of the Graafian follicle, must then, through the nervous system, stimulate the uterus to congestion, with a resulting periodical bleeding. The cessation of menstruation after castration has likewise been cited as proof of the fact that without ovulation there could be no menstruation, since the periodical hyperæmia reflexly caused by ovulation no longer takes place. By others it was considered that the distention of the ovary, occurring periodically, exerted an action upon the vasomotor system, then causing congestion. The atrophy of the uterus after castration was likewise pointed out as a proof of the resulting diminished blood supply, ordinarily furnished by this reflex action of the ovary. On the other hand, it has been frequently stated that the result of castration was due to the tying off of the arteriæ spermaticæ internæ, and that the resulting anæmia was the cause of atrophy of the uterus, and of the diminution in the size of the uterine myomata.

Rein cut all the sympathetic and all the spinal nerves running to the uterus in a dog, and yet the animal bore young. Inasmuch as the uterus, freed from the central nervous system, performed its functions as before, he concluded that a regulating nerve centre exists in the ovaries. All this was taken to prove that menstruation was a result of reflex action originating in the ovaries.

Relation of Ovulation and Menstruation.—As a matter of fact, ovulation and menstruation are related only in that both are the result of the secreting function of the ovary, and are in nowise connected as regards cause and effect. The ovum is the external secretion, the internal secretion entering the blood through the lymph channels. The ripening and expulsion of an ovum may occur at any time. It is, however, a fact that menstruation occurs only after the ovary is capable of producing ripe ova, and whether the egg be expelled, or occasionally degenerate in the follicle, is immaterial. The independence of ovulation and menstruation is evidenced by the fact that the former takes place before menstruation has appeared, and likewise after the menopause, as is proven by cases, by no means rare, of pregnancy in girls who have not yet menstruated, as well as by the occurrence of pregnancy at variable periods after the amenorrhœa of the climacterium. In children the primary follicles develop fully before puberty, and the same development occurs even in the fœtus and in the newly born. Those ova and follicles go through the same stages of development and ripening as in the case of adults. That they are not capable of fecundation is shown by the fact that the ova are only one-half as large as in adults. In those cases, however, of young children with well-developed breasts and genitalia, when menstruation begins there is an unusually strong development of the body, and the ova, as well as the follicles, differ in no way from those found in menstruating adults.

Leopold found that in forty-two pairs of ovaries, thirty pairs showed a corpus luteum belonging to the last menstruation. In thirteen pairs no follicles were found, which on account of their size, or the swelling of the follicle, justified a belief that a bursting of any follicle would have occurred at the next menstrual period. In twelve cases no corpus luteum was found belonging to the last menstruation. One case showed a follicle which had burst between menstrual epochs.

Arnold found that in fifty-four cases, only thirty-nine showed the presence of fresh corpora lutea after the last menstrual period.

Williams found this to be the case in twelve cases out of sixteen. Therefore, ovulation, although in the majority of cases occurring at or near the menstrual period, is not the cause of the same.

Leopold has shown experimentally that in the intermenstrual period follicles ready to burst are present, and that through certain causes, such as coitus, the exit of an ovulum may result at any time. That ovulation occurs during pregnancy is proved in the case mentioned by Kroenig, in which conception occurred as a result of coitus four days post partum. The relatively frequent occurrence of pregnancy during the temporary amenorrhœa of lactation is a proof of ovulation during this time.

Consentino finds that, during pregnancy, lactation and ovulation continue. Although the ovum of a menstrual period may be fecundated immediately thereafter, the ovum usually fecundated is the one given off between four and eight days before menstruation, the egg thus belonging to the period, so to say, first omitted. The ovum retains its vitality for an average period of twelve days, and yet out of a collection of two hundred and fourteen pregnant cases, in sixty-five coitus had taken place after the twelfth day following menstruation. Therefore, in these pregnancies at least, the ovum must have belonged to what may be called the next awaited menstrual period. Even if the expulsion of the ovum occur only a few days before that time, its fecundation is not difficult to explain, nor are the cases puzzling in which one coitus directly after menstruation produces pregnancy, as the spermatozoa retain their vitality for a long time, and have been preserved, in proper temperature, for a period of eight days. Dührssen has found spermatozoa in the tube three and one-half weeks after the last coitus.

It is therefore evident that ovulation, as a rule, occurs from four to eight days before menstruation, but it may occur at other periods, as ripe ova, practically speaking, may be present at almost any time.

Ovarian Secretion.—The periodical swelling of the mucous membrane is due to the secretion given off by the ovary, and the experiment of Strassman proves that the forcing of an additional amount of this secretion into the circulation only enhances this effect. That ovulation and menstruation, or at least the latter, occur with a certain regularity is a fact which we are not able to explain any more than we can say why in malaria the plasmodia are thrown into the circulation at regular intervals, or why the menopause usually occurs at a certain period. At any rate, were menstruation the direct result of periodical ovulation, we should still be in need of a satisfactory explanation for the latter

phenomenon. No other theory is satisfactory than that of secretion. Ovulation and menstruation are evidences of the functional capability of the ovary. Since ovulation may occur without menstruation, but the latter never without the former, we have here an evidence that a certain functional activity of the ovary is necessary to stimulate the mucous membrane to its periodical changes. That after double castration regular bleedings may occur for a certain period is proof of the independent rôle which the endometrium, to a certain degree, plays in the process of menstruation; for sufficient of the secretion of the ovaries may still remain in the circulation to produce the normal processes after removal of the ovaries. The part which the ovaries play in the development of the body, the effect of their presence upon the breasts and the genital tract, at puberty, before each menstrual period, at the menopause, and after castration, are sufficient evidence of their secreting power. The experiments of Knauer and others, to which I shall later refer more fully, prove that it is simply the presence of the ovaries, and the preservation of their secretion, which are of importance to the body, and that their action upon the uterus is in nowise reflex in character, since when removed and implanted elsewhere, and in this way loosened from their connection with nerve plexuses and the nervous system, every sexual peculiarity is absolutely preserved.

It is therefore evident that an ovum, by natural means, may at any time enter the tubes, and that no congestion of the tube, no erection of the tube, and no reflex spasmodic grasping of the ovary by the tube are necessary.

Menstruation is simply an evidence that a fecundated ovum is not present in the tube or in the uterus. Practically no part of the endometrium is thrown off. It seems as if the blood thus lost simply gave an exit to the secretion of the ovary, which, if retained too long in the body, produces in pregnancy certain normal changes, and in a large number of cases abnormal processes. In pregnancy the ovarian secretion stimulates the uterus to enlargement and growth, it stimulates the formation of blood, produces tension and congestion in the vascular system, and stimulates the function of the breasts. After labor, lactation is stimulated by this secretion, so that little or no effect is exerted upon the uterus; therefore it rarely undergoes the periodical stimulation and has a tendency to atrophy. The changes occurring in the decidua menstrualis and the decidua graviditatis are certainly evidences of the action of a secreted substance. The method in which the ovum is embedded in the decidua, and the processes occurring in its immediate vicinity, as well as the fact that in extra-uterine gravidity a decidua graviditatis is formed in the uterus, with decided enlargement of this organ, are likewise proofs of this fact.

Decidua.—The decidua graviditatis shows an enormous thickening of the endometrium. In the first month of pregnancy it is 1 cm. in thickness. Its surface is uneven, deep grooves dividing it into irregular fields. These changes are greatest at the fundus. In the region of the internal os the changes are less noticeable, the lining of the cervix, except for a high degree of hyperæmia, having no part in these changes. The increase of volume in the decidua depends greatly upon the growth of the round cells in the endometrium, and upon their change into decidua cells. The round cells of the connective tissue, situated in a meshwork of spindle- and star-shaped cells forming the stroma, enlarge. The protoplasm increases greatly in amount, and the nucleus becomes larger. These cells appear at first in the upper layer, and so prominently that this layer of the decidua graviditatis is called the compacta, in contrast to the lower layer, the spongiosa, where the glands, although closed, are retained. These cells increase in size from five to ten times, and are found already in the first three months, not alone in the mucous lining, but likewise in the wall of the uterus. That these cells are due to a direct stimulation of ovarian secretions is proved by the fact that they are found in the uterus in extra-uterine gestation, likewise in the mucous membrane of the tube in a normal gestation, occasionally on the peritoneum, on the ovaries, and, in one specimen of mine, were found upon the tube. The glands, in addition to enlarging, show a hyperplasia of the epithelium.

Embedding of the Ovum.—Spee and von Herrf have shown that in the guinea-pig the ovum forms an opening through the epithelial lining of the uterus, and that, after having passed entirely through the mucous membrane, it develops further in the region of the subepithelial connective tissue. The opening thus formed is closed by lymph exuadtion, and there results about the ovum a so-called lymph space, showing that an exchange between the ovum and the surrounding tissue exerts upon the latter a certain reaction. That the same process occurs in the human being is to be expected, for the following reasons: 1. By analogy with the above process. 2. In human beings there is no epithelium, nor are there any gland openings on the surface of the so-called reflexa, facing the ovum. 3. The youngest human ova found in the uterus show no prominence into the uterine cavity, which would be the case if they developed upon the decidua vera, and were enveloped by a decidua reflexa.

Peters examined an ovum supposedly five days old, found in a young girl whose last menstruation was on September 1st, and who at the end of September, with a cessation of menstruation, had among other symptoms, vomiting. Because of her fear of pregnancy she committed suicide on October 1st, and a post-mortem examination, a few hours later, revealed the following condition: The uterus was slightly enlarged and soft. The decidua at the fundus and on the posterior wall was 8 mm. thick; on the anterior, 5 mm. The lining of the cervix was hyperæmic. On the posterior wall was a very sligh prominence, which proved to be the ovum, whose largest diameter was found to be 1.6 mm. The ovum was embedded in the compact part of the decidua, which portion, as before stated, showed only a slight prominence. The summit of the ovum was uncovered by a capsule, but showed a spot of blood granulation.

Only in the immediate circumference of the ovum was there a clear division into compacta and spongiosa. The tissue between the glands near the surface in other parts was slightly increased, so that the early stages of a subsequent division into the two layers were evident. The spaces between the cells were filled with a pale homogeneous plasma, an evidence of the serous infiltration of the endometrium. The nearer to the ovum, the more frequently were free red and white blood cells found between the cells of the stroma and in the plasma. Nowhere was there an evidence of fatty changes in the superficial layers. The mucosa was everywhere extremely vascular. The venous channels showed superficially often only a simple canal of thin endothelium, without adventitia. The arteries preserved their adventitia up to the covering epithelium. The nearer to the ovum, the greater was the vascularization. In this case fecundation took place shortly before the expected menstrual period, confirming the view which Leopold gained through one of his cases, and one which Reichert likewise holds for the same reason. The fact that this ovum had made its way into the decidua, wherein it was firmly embedded, proves, analogous to the observation of Spee, that an ovum can develop only on a spot free of epithelium, and that, through reaction upon the surrounding tissue, an ovum sinks into the decidua, and that this reaction causes a dilatation of the surrounding lymph spaces, with a resulting localized

œdema. This reaction likewise stimulates the decidua to an exchange of products between itself and the ovum, a process undoubtedly aided by the ovarian secretion, with the result that for this reason, and not through a reflex stimulation, the decidua develops further instead of diminishing in size and changing in character, as occurs naturally when, in menstruation, this ovarian secretion is lost.

A further proof of the direct influence which the ovum exerts upon the decidua is shown by the manner in which the space formed by the embedding of the ovum is filled up. There is no possibility, by the way, that an ovum has been taken up in a gland, since the glands are far too small. The character of the œdematous zone about the ovum shows that it is due partly to enormous vascularization, and partly to the accumulation of products of exchange between mother and ovum. The thickened compacta cells are swollen, and there exist wide meshes and spaces separating the individual cells. These spaces are filled with a clear fluid medium in which blood cells are plentifully present. There is, therefore, not alone an infiltration with plasma, but also an invasion of blood elements, which is certainly a proof of reaction. In the edges of the groove in which the ovum is embedded, and also deeper down, a more decided hemorrhagic œdema takes place, and minute blood extravasations force their way up to the epithelium and lift it off. The resulting coagulation, containing likewise the remains of these cells, serves to close the opening and to cover the ovum.

It must, therefore, be taken for granted that the ovum embeds itself in the decidua; and that an active growth of the latter up to and surrounding the ovum, with a formation of the so-called decidua reflexa, by no means takes place.

The stimulative effect of the ovarian secretion upon the endometrium is evidenced by the fact that the decidua in an extra-uterine gravidity possesses all the characteristics of a decidua vera. The reaction produced by the ovum is here also evident from the fact that the intensity of this decidual reaction in the endometrium is dependent upon the nearness of insertion and the grade of development of the ovum. The nearer the ovum is to the ostium uterinum, and the younger the pregnancy, the clearer and more decided are the characteristics of the decidua. In the tube, as a rule, the lining undergoes a like change, but only in the immediate neighborhood of the ovum. At times the other non-pregnant tube shows decidual growth. A further evidence of stimulation is given by the fact that the decidua is rarely thrown off unless the extra-uterine gestation be interrupted.

If, however, it be thrown off, it is not renewed. The throwing off of a decidua occurs, as a rule, only upon the death of the fœtus, upon rupture of the tube, in tubal abortion, or in bleeding into the tube. As the death of the fœtus does not result with every rupture or bleeding, the throwing off of the decidua is an evidence clinically of a disturbance in the process of fœtal development (Winter).

Another of the functions, then, of ovarian secretion is to be found in its stimulation of the round cells of the stroma to growth and to the formation of decidua cells; for these cells are found likewise in certain forms of endometritis with menorrhagia, and in dysmenorrhœa membranacea, in both of which cases we find an over-stimulation of endometrial processes. In the latter especially, the ovarian secretion also stimulates a contraction of the uterus, as in menstruation, in pregnancy, and in uterine dysmenorrhœa, so that the secretion which has in dysmenorrhœa membranacea caused this advanced change in the cells, causes at the same time pains equal to those of labor, with a result that the lining of the uterus is thrown off in parts or in whole. As a matter of fact, this over-stimulation is evidenced by the fact that the endometrium in these cases differs in no way, in the intervals between menstruation, from that of the normal endometrium, and that only at menstruation is found an interstitial endometritis containing these large cells, like those in a decidua graviditatis.

Constitutional Changes.—Were we to consider the relation between the ovary and the uterus, and between the genitalia and other organs to exist through the medium of the cerebro-spinal or sympathetic systems, why should we find the walls of the tubes thin and containing more connective tissue in cases of poorly developed ovaries, and at the menopause, when no primary follicles and no Graafian follicles are present in the ovaries? The uterus then shrinks, the walls become thin and flabby, the mucous membrane atrophies, the connective-tissue elements are more prominent, and the ciliated epithelium disappears. Is it not extraordinary to make the occurrence of these decided changes dependent upon a cessation of ovarian congestion? That these differences are not due to the lack simply of reflex stimulation on the part of the ovary is sufficiently evidenced by the constitutional changes occurring at puberty, at menstruation, during pregnancy, and at the menopause. The relation between the changes occurring at puberty and at the menopause, before menstruation and after menstruation, during pregnancy and after pregnancy, show a decided resemblance. Until shortly before each menstrual period, temperature, pulse, muscular activity, lung capacity, and the excretion of urea increase, and reach their maximum two to three days before the appearance of blood. During this period we find hyperæmia, œdema, increased activity of the ovary, changes in all the mucous membranes, and increased function of the glandular apparatus. The occurrence of swelling of the breasts, tenderness of the abdomen, even pain and the passage from the vagina of increased mucus, sometimes mixed with blood, prove at the beginning of each menstrual period a wave movement, and an increased blood tension by no possibility due to reflex causes. During and after menstruation regressive changes are evident, and the excretion of nitrogenous elements is diminished.

During pregnancy we have an increased amount of the watery elements of the blood, an increased proportion of fibrin, a diminished amount of albumin, an increase in the white blood cells, a relative diminution in the number of red blood cells and in the amount of hæmoglobin.

Before labor the temperature is highest in the last three months of pregnancy, and there is an increase in the elements of the body, equal to one-thirteenth of the body weight. This increase is due to serous infiltration, and to the increased ability of the body to form organized tissue. Post partum, after a temporarily short rise, the temperature is lower, the blood pressure sinks, and becomes normal on the ninth day. The loss in body weight is equal to one-ninth of the weight of the pregnant person. For labor and post partum together, there is a loss of weight nearly equal to one-fifth of the body weight at full term. After labor there is a diminution of tissue change and a diminution in the amount of urine.

Therefore as regards temperature, blood pressure, body weight, the amount of urine secreted, etc., there is always a similar increase before menstruation, and a like decrease in intensity during and after menstruation, as during and after parturition, so that Virchow has well characterized menstruation as being a pregnancy *en miniature*.

According to Loewenthal, who believes that every ovum is embedded in the mucous membrane of the uterus, we may say that labor is a menstruation in which a fully developed ovum is expelled. The co-

incidence of labor with a menstrual period seems therefore natural. The resemblance of the mechanical processes concerned in menstruation and in labor is remarkable, and these changes can be due only to the stimulative effect of the ovarian secretion, acting not alone upon the uterus and the genital organs, but likewise upon the breasts, upon the blood elements, and upon blood tension. This secretion is a stimulus likewise to uterine contractions, and is the probable cause of the contractions normally occurring during labor. The action upon the uterus at the end of pregnancy of this accumulated secretion is probably the cause of labor pains.

The action of the ovarian secretion upon pulse tension, and its effect upon the mucous membranes of the body generally, are likewise evidenced by the congestion of the vocal cords during menstruation, so that during this time the singing voice is poor. The secretion of intestinal mucus is also greater, there is increased perspiration, the lower turbinated bones are swollen, and the eye suffers limitations in power. The best evidence of the constitutional elements involved in the process of menstruation is the occurrence of vicarious menstruation. Under this designation we consider bleedings occurring at regular intervals in a patient suffering from amenorrhœa. The most frequent spot for this bleeding is the nose, usually the lower turbinated bones.

Fleiss described a two-year-old child with well developed pubes and breasts, who had periodical bleedings from the nose. In a second case, a girl fourteen years old, well developed, suffered from regular bleedings from the nose, which stopped, however, when real menstruation began. In another case the regular nose bleedings at intervals of twenty-nine days stopped during pregnancy, only to begin afterward, and after a continuation of eight months ceased again on the occurrence of a second pregnancy. Bleedings of the same kind have been described as occurring regularly from other mucous membranes, the trachea, the lungs, and the stomach. In the latter instance the bleedings were not always associated with vomiting, the blood being usually found in the fæces. In other cases there were bleedings into the thyroid gland. In cases with poorly developed uteri, these bleedings disappeared only when the uterus began to functionate properly.

The secretion of the ovary exerts through the medium of the blood a stimulating effect upon the breasts, noticeable before menstruation, during pregnancy, and during the period of lactation.

Goltz cut through the cord of a dog at the level of the first lumbar vertebra, and later saw the signs of rut appear. After coitus one dead and two living young were born. The breasts were well developed, and lactation and nursing followed the normal course. Since these changes, the sexual tendency and the process of labor, could not have been excited through the cord, it must be that a certain secretion of the ovary, acting through the medium of the circulation, gives the stimulus for the exercise of those functions.

Ovarian secretion exerts a most decided effect upon the development of the uterus and the genitalia, as well as upon the breasts. It is absolutely necessary for the preservation of the developed uterus, the other genitalia, and the breasts. An over-production of ovarian secretion or a disturbance in the function of the ovary causes pathological changes; an under-production of ovarian secretion is likewise the cause of pathological conditions. The production of ovarian secretion and its action for a certain period of time are the probable causes of the pains of labor.

The Trophic Action of Ovarian Secretion.—Halban transplanted the ovaries in newly born guinea-pigs to see what effect transplantation and castration would exert upon the development of the genitalia and the breasts. The comparisons with non-castrated animals are very interesting. In the castrated guinea-pig the breasts were later found to be one-fourth the normal size; the genitalia were small, the vulva was one-third smaller than normal; the uterus was as small as at birth, showing very slight development of muscle and endometrium, and containing no ciliated cells. The breasts showed no glandular tissue, the mammillæ were hypoplastic, the vaginal mucous membrane showed both squamous and cylindrical epithelium—a novel condition. When the ovaries were transplanted under the skin, the uterus was well developed, the tubes were normal, the vulva was large, as were the mammillæ likewise. In the transplantation of one ovary a part of the uterus and a piece of the tube had likewise been taken, and these grew in a normal manner, and increased in size. The transplanted piece of uterus contained well developed muscle and normally secreting glands. The portion of tube showed muscle, epithelium, and ciliated cells. Halban thus showed the influence of the ovary, as a secreting organ, upon the uterus, vagina, vulva, and mamma. He considers it probable that the ovarian secretion acts upon the uterus; the uterine secretion acting in turn upon the mammary gland.

Ribbert implanted the mamma of a young guinea-pig, with its covering of skin, into a cut near the ear. The wound healed, and five months after the operation, the animal having borne two young, this mamma secreted milk normally, a proof that the connection between the breasts and the ovary and uterus is to be found in no other channels than those of the circulation.

Hegar and Kehrer showed that in newly born animals, after castration, the uterus does not develop, but remains at the same stage, or even undergoes atrophy.

Sokoloff castrated rabbits and dogs and found that, a short time after, they became fat and apathetic, and grew constantly worse. Subsequent examination of the uterus divulged muscular atrophy, especially of the circular layer; the vessels were fewer, the walls thicker, the lumen was small and even obliterated. The mucosa, however, remained unchanged. When only one ovary had been removed, there was no change in the sexual development of these animals, the young ones evidencing a normal and constant development of the genitalia.

Jentzer and Beuttner examined the organs of cows within one year to twenty-two months after castration, and found all the layers of the uterus atrophied and substituted by connective tissue. The stratum vasculare had greatly changed, the atrophy of the mucosa, while not constant, was in most cases acute. They castrated rabbits, gave subsequently hypodermatic injections of ovarin, and yet the uterus atrophied. The objections to considering this last procedure conclusive are: 1. That the ovarin of cows was used. 2. That it was given hypodermatically. 3. That there was no sufficient increase in the amounts used. The castration of other rabbits showed that the cylindrical epithelium became lower, the protoplasm degenerated, these processes becoming more defined the longer after castration the animals were examined. The muscularis was found to be atrophied; the larger vessels were gone. Although glands were present, the mucosa showed decided atrophy. In dogs castration produced atrophy of the muscle, but only after three or four months; the epithelium of the uterus was lower, the protoplasma cloudy, the glands were degenerated, and the vessel walls thickened.

Knauer transplanted the ovaries of rabbits and dogs between the fasciæ of the abdominal wall and into the mesometrium, being careful to remove absolutely every bit of ovarian structure. In the mesentery he fastened the ovary with two sutures between two folds

of peritoneum, the ovaries being then nourished through endosmosis or through plasmatic circulation. New vessels grew into the ovarian tissue and furnished its subsequent support; this change began as early as the fourth day. Examination at various periods showed that a small part of each ovary usually degenerated, and new connective tissue appeared in place of the lost cells. In all cases in which a complete degeneration of the ovaries was found, atrophy of the breasts and of the genitalia had occurred. The muscle of the uterus was atrophied, the intermuscular connective tissue was increased, the mucous membrane was atrophied—changes like those which occurred after double castration. Retention of function on the part of the transplanted ovaries was always evidenced by the growth of follicles in a normal manner, by the ripening of the follicles, and by the discharge of the ova. In all such cases the normal character of the breasts, of the uterus, and of the genitalia was preserved, and in the younger animals all these organs underwent a natural development. In one dog with well-developed breasts, thirteen months after transplantation an opening of the abdomen showed the right ovary to be of normal size and to contain three follicles. The left ovary was small. Two months later coitus took place, and after two more months two well-developed young were born. Three years after transplantation had been done, this animal on examination showed externally a normal condition of development of the breasts and the genitalia. The right ovary was the size of a pea and contained follicles; the left ovary was larger than on the previous examination. The right ovary was covered with germinal epithelium; many follicles but no primary follicles being present. A like condition was found in the left ovary. The uterus was normal in every way; the mucous lining contained many glands and ciliated epithelium. The breasts were of normal character, with normal secretion and glands. Knauer's results proved that the preservation to the organism of the functionating ovaries preserves the breasts, the genital organs, and the sexual instinct, a result possible only through the absorption into the circulation of ovarian secretion; and that the function which the ovary exerts upon the body stands in closest relation to its ability to form ripe ova. Ovarian tissue which has ceased to develop ova has lost its other function, that is, secretion. Therefore the numerous nerves of the ovary are in all probability only vessel nerves. Knauer transplanted in sixteen cases the ovaries of animals into each other, obtaining the above good results in only two cases, since in the others the ovaries degenerated. This shows that a certain relation exists between the cells of one and the same body. Although difficult, transplantation of ovaries from one animal to another is possible.

Morris removed the adnexa in a patient and sewed a piece of one ovary into the stump of the right tube. One month later the patient became gravid, aborting in the third month. Into a twenty-year-old girl with uterus infantilis and rudimentary adnexa, with suppressio mensium, he transplanted a piece of the ovary of a thirty-year-old patient, fixing it in the fundus of the uterus. Eight weeks later a profuse menstruation, lasting ten days, occurred; after six weeks a normal one lasting five days; the third one five days later. The fourth and fifth menstruations were normal, at intervals of four weeks.

Glass transplanted an ovary of a seventeen-year-old girl into a twenty-nine-year-old patient from whom both ovaries had been removed two years before. The ovary was fixed in its normal situation through an opening in the sack of Douglas, per vaginam. Sixteen days later occurred a bleeding lasting two days; six months afterward a menstruation of three days; eight months after operation the patient showed good color, was of good appearance, with a return to former mental and body conditions, after two years of artificial climax.

Dudley implanted an ovary into the fundus of the uterus after removal of a pyosalpinx duplex, and regular menstruation continued.

An examination of the uterus after castration in women shows an atrophy of the cervix, an immediate atrophy of the corpus, a sclerosis of the vessels, which show a growth of the intima, and an endarteritis obliterans, especially in the larger vessels. Few glands are present, and the connective tissue is increased.

Gottschalk found an exceptional condition in one case, in which the muscularis was well preserved, although the mucous lining had almost entirely disappeared.

Cholmogoroff found the uteri at climacterium to contain a large amount of connective tissue, the vessels being greatly sclerosed. I have found the same condition in a high degree in two cases of my own.

A normal menstruation is absolute evidence of the presence of a normally functionating ovary. The abscence of ovaries, a poor development of these glands, an insufficient secretion of ovarian substance, or a diversion of ovarian secretion to other organs of the body, always causes a failure of uterine development or uterine atrophy. It is possible that, with partial or total absence or atrophy of the uterus or other genital organs, normal ovaries may be present. It is likewise possible for poorly developed ovaries to be the result of a failure of development of the body in general or to be simply a failure of development of the ovary itself, through embryonal disturbances.

Winckel has shown that, in the development of the uterus and tubes, the situation of the Wolffian body close to the ducts of Müller may influence, to a very great degree, their growth and is a frequent cause of malformation. The early completion of the Wolffian bodies, their opening into the sinus urogenitalis, the growth of the Müller's ducts along the Wolffian, and their crossing at that spot where the union of Müller's ducts finds its upper limit, are anatomical embryological factors easily recognized as causes of uterine maldevelopment and hypoplasia. Further, the origin of the ligamentum ileo-genitale rotundum at this upper limit, its close union with the ducts of Müller, the fact that its line of development in a measure opposes the union of the ducts, in addition to tension, pressure, and torsion exerted by the neighboring organs, such as the Wolffian bodies, the bladder, the ureters, the vessels and nerves of the uterus and rectum, are important factors influencing the development of the uterus. In addition, Winckel recognizes the occurrence of abnormal cells in the septum between the ducts of Müller, and general hypoplasia of the vessel system, as additional causes of maldevelopment. Aside from secondary atrophy, the result of constitutional diseases, the embryological causes here mentioned, and the forms associated with general hypoplasia, we recognize in the ovary and its secretion the factor which governs the development of the uterus, the genitalia, and the breasts, and the factor which is concerned in the preservation of these organs and the regulation of menstruation.

Eberlin describes a patient with vaginal defects, who, in her eighteenth year, had vicarious menstruation from the nose at regular intervals for six months, after which no recurrence was noted. Her mammæ and external genitalia were small. She suffered from molimina menstrualia every three weeks, at first for periods of three to four days. Eventually severe pain was experienced constantly, associated with sickness at the stomach and vomiting. Laparotomy divulged a uterus rudimentarius, with absence of the adnexa of the

left side. The right tube and ovary were almost normal. The uterus was 3.5 cm. in length, differing microscopically in nowise from the normal as regards muscle, but possessing no cavity. The ovary showed a thickening and a hyaline degeneration of the vessel walls. In addition to the corpus luteum, very few follicles but no Graafian follicles were present. After castration all the annoying symptoms disappeared.

Fritsch operated in a like case in which severe molimina menstrualia, sickness at the stomach, and rectal bleedings were the indications.

In all, Eberlin finds twenty-one cases of this sort associated with vaginal defect to have been operated upon. The ovary in the above-cited case of Eberlin, though containing few follicles, nevertheless secreted sufficiently to cause the severe symptoms. Since no endometrium was present, and no excretion by that channel took place, the ovarian secretion, through cumulative action, was responsible for the severity of the pain. Whatever part the uterus took in these attacks must have been the result of uterine contraction, since congestion alone is not responsible for so much pain, as is evidenced by the absence of such suffering in pure congestions of the uterus, associated with metritis, etc.

Amenorrhœa.—Under amenorrhœa we group those cases which show an absence, a too late appearance, or a too early cessation of menstruation. In these cases we find: 1. An atrophy or poor development of the uterus, which is of two kinds—concentric, the severe form, and eccentric, usually temporary. 2. An absence of the uterus with or without the presence of normal ovaries. 3. Uterus fœtalis. It may be taken for granted, if the ovaries on examination are found to be present and large, and if molimina menstrualia occur, that the ovaries are not at fault, but that the condition is due to the causes mentioned by Winckel, or to a general hypoplasia. 4. The amenorrhœa so frequently a symptom of chlorosis, in a large number of cases due to a temporary functional inactivity of the ovary. 5. The amenorrhœa of lactation, accompanied by hyperinvolution, in all probability due to the fact that the ovarian secretion, diverted to stimulation of the mammæ, fails to act sufficiently upon the uterus. 6. Amenorrhœa is not infrequently said to be the result of adiposity, and on the other hand adiposity occurs, as a rule, after the menopause or after castration. As a matter of fact, in both these cases, adiposity is partly the result of a failure of sufficient ovarian secretion, the amenorrhœa then being an evidence of this failure.

In the case of poorly developed ovaries, menstruation, if present, is usually unaccompanied by pain, and the girls have irregular, weak, or eventually no menstruation. Although these persons are well developed, yet they show poorly developed genitalia. In connection with small ovaries is found a small uterus, the breasts being well developed, but containing little glandular tissue. There is a tendency to fat, which distinguishes these individuals from those with well-developed genitalia.

Uterine Atrophy.—Under atrophy of the uterus belong strictly only those cases in which the uterus was previously normal in size, with a cavity of normal length. These cases are seen: 1. At menopause. 2. At climacterium præcox, artificial or natural, and always associated with the symptoms of the climacterium. 3. In lactation atrophy. The changes found in the first two classes have already been described. The changes occurring in lactation atrophy are: *a*. Concentric with a cavity of 5.5 cm. or less; *b*. eccentric, with a cavity of normal size but with a deficiency of muscular elements. These latter cases are not infrequently associated with small adnexa. As an evidence of the part which ovarian secretion plays in stimulating the metabolism of the body, it may be mentioned that the majority of nursing women who have a uterus under the normal size show all the evidences of poor nutrition, and especially laxity and flabbiness of the general body structures. In "prematurely aged women" lactation is poorly borne. It is in these cases that Frommell finds the greatest amount of uterine atrophy, and he supposes it to be an evidence that nursing deprives the body of a large amount of nutrition. It is true that the ovarian secretion, diverted almost exclusively to stimulating the process of lactation, deprives the body of great support, as is evidenced by the improvement in these persons after stopping lactation. It is likewise true that the subsequent improvement is due to the fact that the ovarian secretion then exerts its force upon the body functions in general; for I believe that by no means so much energy is involved in the process of lactation as in the process of pregnancy, and it is an ever-existing marvel that the majority of these women show all evidences of stimulation of every bodily function during pregnancy, a stimulation which can be attributed only to the tonic effect of the ovarian substance.

Thorne considers lactation atrophy to be a reflex trophoneurosis, and believes that every nursing amenorrhœic woman has a hyperinvoluted uterus, without, however, an involvement of the ovaries. He acknowledges the frequency of anæmic conditions associated therewith, but observes that those cases menstruating during nursing show no atrophy of the uterus. This associated menstruation is an evidence of sufficient ovarian stimulation.

Engstrom saw atrophy only in anæmic, or poorly nourished cases, and I believe the diminished function of the ovary, and its diversion to other centres, to be the causes of the anæmia and the atrophy of the uterus. On the other hand, galactorrhœa is a significant proof of this statement of stimulation by the ovary through the medium of the circulation; for so soon as menstruation occurs galactorrhœa ceases. Abegg overcame this affection in one case by the use of hot vaginal douches, which had the effect of causing menstruation.

Gottschalk overcame a lactation atrophy of the uterus and an associated galactorrhœa, by dilatation of the uterus, and through energetic scarification of the portio. As a further evidence of the value of ovarian secretion to the uterus and its lining, may be considered its function in stimulating uterine contraction. When poorly developed ovaries are present, with ovarian changes at the climacterium, and after castration, the muscular wall and the mucosa atrophy. The fact that the presence of normal ovaries preserves uterine muscular tone is sufficient in itself to warrant the statement that the ovarian secretion must exert an influence upon uterine contraction.

Dysmenorrhœa.—In dysmenorrhœa either the muscle wall or the mucosa may be at fault. Dysmenorrhœa means a painful feeling or decided pain before or during menstruation. Leaving out those cases coming under the head of dysmenorrhœa parametralis or peritonealis, we have among uterine forms those showing a stenosis of the cervix. Leaving out those cases in which, with a movable and well-developed uterus, there is a decidedly sharp anteflexion, the stenosis is usually found at the internal os. On the whole, contrary to general opinion, simple stenosis is rarely the cause of dysmenorrhœa, and only those cases cured by dilatation can be positively accepted having been so affected. The other cases include those with poorly developed uteri, or those showing local changes or hyperæsthesia of the endometrium. The former include all degrees, from decided atrophy to those cases in which, in spite of poor development, improvement occurs after marriage or after conception.

In part of these cases in which embryological disturbances have caused a hypoplasia of the uterus, but in which the ovaries are well developed, the ovarian

secretion not alone stimulates the muscular contraction of the uterus, but also causes a congestion of the mucosa, with its small vessels. In these cases the pain is naturally great, as the congestion is relieved slowly. In those cases of dysmenorrhœa occurring in chlorosis, we have, through delayed development of the ovaries, and through temporarily insufficient secretion, an insufficient development of the uterus. That in these cases the dysmenorrhœa is the result of uterine stimulation is evidenced by the fact that very often dysmenorrhœa does not occur during the first appearances of the irregular menstruation, but appears often years later when, with the development of the uterus, the congestion gradually becomes greater. This form, however, rarely occurs after marriage, if not present before. In those individuals in whom a pure hyperæsthesia of the endometrium is present, we must consider the local condition to be a result of insufficient local trophic stimulation, since very frequently in these cases there is an involvement of the entire nervous system. Since, however, the other cases of stenosis do not show this local sensitiveness of the mucosa, we must consider contraction of the uterus to be the common element in dysmenorrhœa; for only such treatment as brings about a freer flow of blood from the mucosa itself gives relief. It is generally known that the smaller the amount of blood lost the greater the pain, and, as a rule, simple stenosis is not the real cause. Dysmenorrhœa membranacea certainly speaks for ovarian stimulation of the uterus, physically and trophically; for the birth of the membrane furnishes us with two conditions usually found only in pregnancy. 1. Acute and continued contractions of the uterus, which expel the membrane in pieces or as a whole. 2. A membrane containing a large growth of decidua cells.

The frequent occurrence of amenorrhœa and uterine hypoplasia in chlorotic girls is an interesting link associating the ovary as a secreting organ with the vital functions of the body.

Chlorosis.—Chlorosis is an illness occurring exclusively in girls, most frequently during the years of development and the years immediately following, and showing a tendency to recur. It develops spontaneously without evident cause, and has no connection with conditions relating solely to nutrition, since its occurrence among the better classes is very frequent. It affects directly only the condition of the blood, without causing constitutional degeneration, and without great injury to the general nutrition. Chlorosis is a disease, and not a symptom of a disease. Such patients as lose weight, with evidences of general weakness, have these symptoms as a result of complications. Heredity plays a part, since not infrequently the mother as well as sisters have suffered in turn. The cardinal symptom is anæmia, showing a diminution in the number of red blood cells and a decided diminution in the amount of hæmoglobin. This condition must be distinguished from the chlorosis associated with hypoplasia of the vascular system; for chlorosis is a curable affection while the latter is not. No theory with regard to chlorosis which leaves out of consideration its occurrence in girls only, at the time of, or in connection with, sexual development, deserves attention. It occurs most frequently between the fourteenth and twentieth years. According to Niemeyer, such cases as occur after the twenty-fourth year are almost never chlorosis.

Von Noorden believes the stimulation which the ovary exerts upon the blood-forming centres to be one of its important functions. This action is not exerted reflexly, but through the channels of circulation by means of the ovarian secretion. There is in chlorosis a relative and absolute increase in the number of eosinophile cells. In osteomalacia, Neusser found a change in the number of the eosinophile cells. Upon recovery after castration they are diminished in number. Since osteomalacia is due to an oversecretion or a malsecretion on the part of the ovaries, these changes in the blood speak for the contention of v. Noorden. Further, Neusser believes the skin to be an important blood-forming centre, and considers the ovary and skin to stand in most intimate functional relation. If, then, the ovarian secretion exerts a trophic influence upon the skin, we can understand the frequent occurrence of skin affections, associated with menstruation and its disturbances.

In chlorosis there is often associated a poor development of the genitalia. The pelvis in a certain proportion of cases is of the child's type, in others there is a poor development of the external genitalia, or a uterus infantilis, small ovaries, poorly developed breasts, etc. Seventy-four per cent. have failures of genital development of one form or another. Among non-chlorotics these conditions are found in only twenty per cent. Menstruation is, as a rule, disturbed. During the chlorosis there is very frequently absolute or relative amenorrhœa. Those affected with menorrhagia always show a decided change in the mucosa. In all, seventy-seven per cent. present a weakening of the menstrual function.

A justification for the statement that chlorosis is due to diminished ovarian secretion is furnished by the effects of ovarin therapy in these cases.

Bestion de Camboulas obtained excellent results in amenorrhœa and chlorosis.

Saalfeld found the results obtained by this method exceedingly valuable in the treatment of affections associated with chlorosis.

Seeligman obtained excellent results, especially in chlorosis, likewise Touvenaint.

Jacobs and Dalché speak for the splendid improvement obtained by the use of ovarin.

On the other hand it may be considered that chlorosis, with a failure of proper stimulation of the uterus and its lining, in causing a diminished menstruation, prevents thereby an excretion through the menstrual blood of toxins produced at puberty. There may likewise, at this stage, be a certain antagonism between the thyroid gland and the ovary. Since many of the cases of chlorosis present symptoms not unlike those found in Basedow's disease, it is possible that a too greatly diminished secretion of ovarian extract causes a relatively increased amount of thyroid extract to circulate in the blood. For this speak the good results obtained by Seeligman and others, in the treatment of typical morbus Basedowi with ovarin. The ovarian secretion is a stimulator of blood formation, and causes a congestion of the genital organs. Thyroid extract, on the contrary, causes anæmia of the genital organs, as is seen in the good results obtained by the treatment of uterine fibroids with thyroid extract. It is possible that those chlorotic patients who take on fat have not alone a diminution in the function of the ovary, but likewise a diminution in the function of the thyroid, while those suffering with the symptoms of morbus Basedowi, have a diminished secretion from the ovary, but an oversecretion on the part of the thyroid gland.

The symptoms caused at the climacterium, artificial or natural, are certainly due to diminution or absence of function on the part of the ovary, as is proved by the good results obtained by treatment with ovarin.

Seeligman obtained excellent results in treating fifteen cases of castration menopause, and affections of puberty, with ovarin.

Touvenaint saw decided improvement in six cases of castration menopause and two cases of natural menopause.

Jouin publishes excellent results with ovarin, for

morbus Basedowi, for artificial and natural menopause, and for atrophy of the genitalia.

Mainzer, in the clinic of Landau, found that disturbances in the vasomotor system, resulting after castration, disappear upon the administration of ovarin, that disturbances after the natural climacterium are benefited, that the results in primary or secondary amenorrhœa are satisfactory, but that no effect is exerted upon general hysteria.

After castration, the reduction of oxygen exchange amounts to twenty per cent., the general gas exchange being likewise diminished; the weight, as a rule, increasing. The effect of ovarin if given within two and three months after castration not only overcomes this change, but increases the gas exchange above the normal, this increase lasting a variable time, and diminishing gradually. On normal animals no effect is observed. The use of preparations obtained from the male organs exerts no effect on the female deprived of ovaries.

Osteomalacia.—A further evidence of the influence of ovarian secretion upon the body in general may be found in its relation to osteomalacia, occurring as it does so frequently in pregnancy. Siegert described four cases observed in children, and verified upon autopsy, proving that it affects growing bones as well as the completely developed skeleton. He finds phosphorus to be powerless against rhachitis but to be a specific in osteomalacia. Heubner likewise finds pnosphorus of no value in rhachitis, since the latter is a condition due to non-calcification. Siegert considers osteomalacia to be a loss of calcium salts in already formed bones.

Ringel found in the literature only two cases of osteomalacia in men; his own case was verified upon autopsy. Hahn found in the literature forty-two cases occurring in men. Of these only five were bettered or cured.

Schnitzler found twenty-four cases in the literature of Wuerttemberg, occurring once in a man, once in a child, twice in nulliparæ. It occurs in far the largest number of cases in women during or after pregnancy.

Following the analogy of the supposed reflex action from the ovaries as the cause of menstruation, Fehling, who found that castration was of decided value in this affection, considers it to be a trophoneurosis. Ferrione found the ovaries in two cases to be larger than normal. They contained small hyaline spots, the vessels of the stroma were increased, their media and adventitia thickened and degenerated in spots.

Heyse found in the ovaries of his patients an abnormal richness in dilated arteries and capillaries, whose walls showed hyaline degeneration of the media and intima. He found a diminution in the number of follicles, a condition which Hofheimer denies.

Schnell found the ovaries in his cases to be small, with a disappearance of follicles, a degeneration of the connective tissue, and hyaline degeneration of the vessels in the stroma. The more severe the affection, the greater was found to be the degeneration. He distinguishes two forms—the slow, and the progressive. The former usually occurs during pregnancy, with a tendency to improvement after labor. The progressive form is not dependent upon gravidity, since it also occurs in nulliparæ. This form goes on without cessation, and furnishes the most severe cases. He finds that multiparæ have no predisposition to this affection; on the contrary, the more labors that have taken place, the less the tendency. The earlier the affection appears, the worse is the form. It occurs usually between the thirty-seventh and forty-fifth years.

Consentino finds that the affection makes its greatest progress in those cases in which ovulation continues during pregnancy. The generally accepted view is that the fertility of these patients is very great, which seems to speak for an oversecretion, or a malsecretion on the part on the ovary. At any rate, although the slighter forms may recover spontaneously after labor, or may be improved by baths and by the administration of phosphorus, by far the larger number are to be benefited only by castration.

Frey considers one of the advantages of castration to be the prevention of pregnancy, since these patients seem to be decidedly fertile. He rejects the theory of a bacterial cause, and gives a list of thirty-five cases on whom the operation of Porro was performed, and five cases of sectio cæsarea with castration. Of these two died of ileus, two of peritonitis, one through uterine rupture. The results judged within a period of two months to three years were either good, improved, or cured, with the exception of one patient of Beaucamps, who had a recurrence after two years.

Orthmann speaks of excellent results in eighteen cases. Piretti observed an increase of 20 cm. in length in one patient, five months after castration.

Consentino claims for castration decided benefits, even in non-puerperal cases.

Eckstein recommends the phosphorus treatment for light and medium cases, and in cases at or near the climacterium. For the severe cases, castration gives decided results, but only in menstruating women.

Schnell treated sixteen patients with cod-liver oil and baths, with such good results that no operation was necessary. In eleven cases of the severer form castration was performed. In four acute cases, at the end of gravidity, the Porro operation was done. Of these patients, six castrated and one Porro were cured. The other castrated patients and another Porro were probably cured. Two of the Porro cases terminated in death as a result of the operation.

A list of one hundred and twenty-five cases of osteomalacia in which the ovaries were removed shows that seventy-two per cent. of the patients are cured, twenty-three per cent. improved, with no effect in five per cent. (Günther). Truzzi found in ninety-seven cases that eighty-three per cent. of the patients were cured by removal of the ovaries.

Eclampsia.—The two theories as to the cause of this condition are those of Veit and Fehling. Veit considers it to be a bacterial infection. Fehling considers it to be an auto-intoxication, for which the products given off by the fœtus are responsible, giving as one reason for this theory the frequency and severity of the attacks in twin pregnancy.

Ludwig and Savor have found that the poisons given off in the normal urine are diminished in pregnancy, but are increased in amount and virulence after labor, especially in cases of eclampsia. The blood serum, however, in gravidity is more toxic than in non-pregnant cases, being especially poisonous in eclampsic patients. Therefore, there circulates in the blood during eclampsia a toxic substance, the supposed cause of the convulsive seizures. Before a seizure there is, as a rule, oliguria or anuria. The presence of albumin in the urine of these cases is to be considered the result of this toxic action, rather than the cause, since very frequently the kidneys are affected without any annoying symptoms, and on the other hand these cases occur with no involvement of the kidneys whatsoever.

Primiparæ are more frequently affected than multiparæ. Twin pregnancy seems to predispose to this affection. It has been found that these attacks occur more frequently, and to a severer degree, in cold and humid weather—a fact which speaks for the retention of toxins through diminution in the function of the skin. In a tabulation of three hundred and sixteen cases, sixty-two attacks occurred shortly before labor, one hundred and ninety during labor, sixty-four after labor. Another tabulation of four hundred and fifty-

three cases gives thirty-eight cases as occurring before labor, two hundred and ninety-two during labor, and one hundred and twenty-three after labor.

Stroganof found among forty-five cases that twenty-four occurred before, and twenty after labor. The fact that, with the exception of a few isolated cases, this condition occurs at full term, and the fact that not infrequently uterine contractions during the seizures are extremely severe, speak for the existence in the blood of a substance which is intimately connected with the process of parturition. Since the ovarian secretion is the cause of menstruation, itself a process like labor, it is only a natural conclusion that this ovarian secretion is likewise a cause of those changes through which labor is brought about. And it is a logical sequence that this same substance or a product of it is the direct cause of eclampsia.

Chorea.—Chorea is a disease affecting chiefly children, and occurring in a severe form in pregnancy. Over seventy per cent. of the non-pregnant cases are females. After puberty the percentage in females increases. This disease is most common between the ages of five and fifteen. A choreic patient may become pregnant, but more frequently the disease occurs during pregnancy. According to Osler, Buist has tabulated two hundred and twenty-six cases in pregnant patients. Of these, in six chorea preceded the pregnancy; in one hundred and five it occurred during pregnancy; in thirty-one in recurrent pregnancy; forty-five cases terminated fatally, and in sixteen cases the chorea developed post partum. Beginning in the first three months were one hundred and eight cases, in the second three months seventy cases, in the last three months twenty-five cases. In eight cases there was a history of attacks of chorea in other members of the family.

The predominance of the disease in females, its onset in children near or at puberty, its frequent occurrence in pregnancy, and the resemblance, in some degree, of its symptoms to those of eclampsia, justify the theory that this affection has a relation to the quality or to the amount of the ovarian secretion, especially as it occurs so often at a period when the ovary begins to assert its decided interest in the development of the body. The occurrence of chorea, at this period, in girls bears a resemblance to its occurrence in pregnancy, for in the latter instance, as it makes its appearance during the first three months of gravidity, it seems likely that we have an action due to a suddenly increased or altered amount of ovarian secretion.

The relation of the ovary to the normal functions of a special character in women is decidedly clear; its relation to pathological states is highly probable. The weaker sex with its tendency to these affections and to hysteria will probably in the future be less frequently treated as possessors of nerves alone. It is not probable that ovarin replaces all that the ovaries should furnish, nor can ovarin in a short time overcome injuries long existing; that its action in the above-mentioned affections, verifying, as it does in a measure, the results of animal experimentation, may lead to a more rational treatment of certain diseases in the female, both medically and surgically, is not to be doubted.

127 East Sixty-First Street.

Prognosis of Locomotor Ataxia.—I am of the opinion that with many a too gloomy prognosis is made. In my experience the arrest of the disease is not infrequent when the treatment is commenced in the preataxic stage, and considerable improvement is possible even when the second and third stages of the disease have been reached prior to its commencement. —Brower.

THE USE OF SUPRARENAL CAPSULE IN HÆMOPTYSIS.

By WM. B. KENWORTHEY, M.D.,

MILFORD, PA.,

COUNTY MEDICAL INSPECTOR, STATE BOARD OF HEALTH.

Not a few articles have lately been published in regard to the use of suprarenal capsule in the control of hemorrhage from the eye, ear, nose, and throat, and a few instances of its successful employment in uterine hemorrhage have also been cited, but, so far, very little seems to have been said in regard to its use in hæmoptysis.

The necessity for a prompt and reliable remedy, free from toxic or unpleasant after-effects, to control hæmoptysis is never more thoroughly realized than when one is called suddenly to treat a profuse hemorrhage from the lungs in a patient who has previously shown no marked signs of pulmonary disease.

This emergency, although fortunately comparatively rare, was amply exemplified last summer in a case that came under my care, in the following way:

A. F——, who had apparently always enjoyed fairly good health, aside from a slight cough that had never aroused any suspicions, came to Milford with his family to spend the summer.

After a somewhat protracted bicycle ride, he suddenly experienced a violent attack of coughing, which at first appeared to be free from any expectoration. In the course of the next ten minutes, however, he began to bring up large mouthfuls of clear, frothy blood. This continued for about two hours and a half, and was attended with the loss of nearly a pint of blood, although opium, ergot, and gallic acid were administered, ice was applied to the chest, and absolute rest insisted upon.

The following day the hemorrhage began again about 4 P.M., and about two hours later, not quite so much blood being lost as on the preceding day. The treatment was the same as before, the opium and ergot having been given continuously every three hours since the first hemorrhage.

On the day following the hemorrhage began at 10 A.M. I saw the patient about an hour afterward, and found him in the following condition: Pulse, 140, weak and irregular; temperature, 102° F.; respiration, 40, and hemorrhage still continuing.

There were some consolidation at the apex of the left lung, harsh bronchial breathing over the upper part of the chest on both sides, and innumerable moist and bubbling râles anteriorly and posteriorly in the lower lobes, presumably from blood in the air cells.

I gave him suprarenal capsule in three-grain powders, one every half-hour, until three were taken; then one every two hours, until three more were taken; then one three times daily for one week, to be taken dry on the tongue, chewed and swallowed without water.

The first powder was taken at 12 o'clock, and in less than five minutes the hemorrhage had ceased entirely, and did not return at any time during the next ten weeks that he was under my care. On making a second visit that same evening, I found the pulse down to 90, strong and regular; the temperature, 101° F., and respiration, 28.

The day following the pulse was 80, full, strong, and regular, very similar in character to a digitalis pulse; temperature, 99.4° F., and respiration, 28.

When he left Milford some two months later, his pulse had been 75 to 80 for some time, which would lead me to believe that the action of suprarenal capsule on the heart is more permanent than is generally supposed, as this observation was made at least six weeks after the drug had been discontinued.

One peculiarity noticed in this case was the reversal of the usual rise and fall of temperature, morning tem-

perature being 99° to 99.4°, and evening temperature normal.

There was a gain of eighteen pounds in weight during the ten weeks' stay in Milford, and, in my opinion, the suprarenal capsule, by stopping the hemorrhage immediately, contributed largely to the subsequent improvement.

In fourteen cases in which the suprarenal capsule was given to control hæmoptysis, in no case did it fail to accomplish its purpose, and in only one case did the hemorrhage continue for fifteen minutes after the administration of the first powder, the subsequent doses, although probably not absolutely necessary, being given as a precautionary measure, as the drug seems to have no deleterious effect, even when its administration is continued for a considerable length of time.

In each and every case there was a decided strengthening and slowing of the pulse, a lessening of the cough and expectoration, and a marked improvement in respiration. To sum up, I should say that suprarenal capsule is the most prompt, surest, safest, most reliable drug that we have at our command for the control of hæmoptysis, and that its possibilities for the future are many and varied.

Post-Influenzal Tracheal Hemorrhage.—James Donelan describes a series of cases presenting the common symptom of hæmoptysis in connection with grippe, but in which no diagnosis of tuberculosis could be made from the evidence at hand. It was found, on careful examination, that during the attack the trachea was coated with blood which appeared to be uniformly spread over its mucosa. As the acute phase passed away, the upper part of the trachea was coated with clotted blood more or less uniformly or in the shape of tear-like clots. When the bleeding had nearly ceased, the larynx, including the vocal cords, was seen to be generally congested. It was, however, in the subglottic region that the greatest abnormality was observed. The trachea from the sixth ring up was intensely congested, and a close plexus of submucous dilated vessels could be seen occupying the intercartilaginous spaces, and in some places crossing over from one space to the next above or below. Sometimes the examination provoked cough, and then blood was observed to ooze forth in this direction, and it was plain that it did not come from any point farther down, as it was possible to see the windpipe to the bifurcation. Except for the above condition, there was no other evidence of respiratory disease, and it became clear that the cases were of influenza complicated with tracheal hemorrhage.—*Journal of Laryngology*, January, 1901.

Notes of a Case of Sclerema Neonatorum.—E. Alan Mackay reports the case of a child born May 28, 1900. This infant was a girl, and the tenth child. All of the other children have been healthy since birth. The child was very much cyanosed at birth, but was resuscitated. When she was about a week old the skin over the upper part of the back was hard and thick, and when at three weeks old she was brought back to the hospital, there was marked induration of the skin over the back from the lowest ribs upward. There was no pitting. The edges of the induration were clearly defined. The centre of the indurated area was of a dull red color. The affected skin had a waxy feeling. Pressure did not appear to give pain. The treatment consisted in daily inunction with five-per cent. ichthyol ointment, and gr. $\frac{1}{16}$ hydrargyri subchloridum three times daily. As there was no improvement, the mercury was discontinued and mistura cinchonæ given instead. As this caused retching, quinine in gr. $\frac{1}{8}$ powders was given: this also caused sickness and was stopped, only local treatment being kept up. On June 30th the induration was much less, and the discoloration was gone. A fortnight later all trace of it had disappeared, and the child was thoroughly well, and has remained so ever since.—*Intercolonial Medical Journal of Australasia*, December 20, 1900.

The Real Value of Quinine in Labor.—M. H. Fussell strongly urges that quinine be used in all cases of multiparæ, when labor has actually begun, and when the pains are slow and ineffectual and the os is fairly well dilated. In fifteen minutes to half an hour the pains will increase in frequency and strength. If there is no obstruction the labor will be speedily terminated. The employment of the drug will frequently obviate the use of forceps in uterine inertia. Necessarily it should not be used, and valuable time lost, when the failure of the head to engage is due to malpositions or to some disproportion between the sizes of the head of the child and the pelvis of the mother.—*The Therapeutic Gazette*, January 15, 1901.

Arsenic in Food and Drink.—In regard to the recent disclosures made in England as to the presence of arsenic in the beer of certain breweries, an editorial calls attention to the fact that legislation directed against "arsenic in beer" would be of too limited a nature to protect the public. The glucose from which most of the arsenic has been derived, is extensively used in the manufacture of sweetmeats, confectionery, jam, and other articles. Nothing is more probable than that a maker of arsenical glucose with a stock on hand no longer salable to brewers, would endeavor to dispose of it at a reduction to jam makers, in the hope that the quantity consumed would be too small to produce any deleterious effect.—*The Hospital*, January 19, 1901.

Affections of the Heart Substance.—Thomas E. Satterthwaite classifies the following varieties under the simple heading "Diseases of the Heart Walls." 1. Fatty changes—(*a*) degenerations, (*b*) depositions. 2. Simple hypertrophies as caused by (*a*) severe exercises—voluntary; (*b*) pregnancy; (*c*) vascular obstruction, including aneurisms and atheroma; (*d*) unusually small vessels, congenital, acquired; (*e*) the emotional or neurotic heart; (*f*) the heart in mechanical injury. 3. Simple dilatations as caused by (*a*) infections, (*b*) anæmia, etc. 4. Atrophies of the heart. There exists both physiological and pathological cardiac hypertrophy. Among the writer's records of the latter class the majority are hypertrophies of the left ventricle due to defects in the aortic or mitral valves. There is a form of large heart seen in hysteria and various nervous affections, which might be called the neurotic heart. It is apt to be complicated with valvular difficulties. The tobacco heart is apt to be enlarged. There is a close relation between cardiac hypertrophy and dilatation and they often coexist (eccentric hypertrophy), though not always. Atrophy of the heart is less common than hypertrophy. Syphilis of the heart has been recognized from very early times. Any part of the heart may be diseased. It is more common in the male sex, and is usually seen between the ages of twenty and forty. The prognosis is bad but not altogether so. Sclerosis may lead to cardiac aneurism, the sclerotic or fibroid tissue yielding under the contractions of the organ so that the heart walls bag out. Spinal deformities cause mechanical embarrassment to the circulation, leading at first to hypertrophy, possible distortion of the valves, and, eventually, to heart failure.—*The Post-Graduate*, January, 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 16, 1901.

REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THIS report, like that of the army, grows more bulky and covers more ground each year. The naval forces of the United States, during the period of which the report treats, have been as usual scattered in various parts of the globe, but the large proportion of the war ships have been serving on the Asiatic station, owing to the situation in the Far East. The Philippines have naturally been the headquarters, and the health of the squadron there, considering the climatic conditions and the necessary exposure, is stated to have been remarkably good.

The health record of the navy and marine corps for the calendar year 1899, shows a marked decrease in the ratio of admissions to the sick list per 1,000 of strength, when compared with the previous report, despite the continued presence and prolonged cruising of ships in tropical waters and the occupation of shore stations in tropical possessions. The ratio during the past year was 783.08 as against 871.69 in 1898, 838.53 in 1895, 775.75 in 1896, and 748.24 in 1897.

The average strength of the active list for the year 1899 was 20,819. The average strength of the force afloat was 13,519 distributed as follows:

North Atlantic Station, 6,588; South Atlantic Station, 423; Pacific Station, 4,652, and receiving ships, 1,856. The total number of admissions for disease was 12,794, and for injuries 2,955, giving a ratio per 1,000 of strength of 636.11 and 146.92 respectively. The ratios for 1898 were 695.42 and 176.27. The daily average of patients was 645.82 and the ratio per 1,000 of strength 32.11 as against a ratio of 29.46 in 1898. The total number of sick days was 235,725, giving an average of 11.22 days for each man of the navy and marine corps, and 14.97 days as the average duration of treatment per case. In 1898 the corresponding averages were 10.75 and 12.33 respectively. There were 153 deaths during the year, of which 95 were from disease and 58 from injuries (including poison). The death rate was 7.35 per 1,000 of strength. The death rate per 1,000 of strength in 1898 (exclusive of the *Maine* casualties) was 7.21.

Malarial diseases head the list as regards the number of sick, there being 943 cases; however, there were only two deaths from maladies of this nature. Diarrhœal affections amounted to 900 with 3 deaths. Gun-shot wounds were responsible for 884 cases of disablement, the deaths resulting from these injuries being 21. Rheumatic affections numbered 716; the deaths from acute articular rheumatism were but 2. Bronchial affections accounted for 685 cases of sickness, 3 of which proved fatal. Epidemic catarrh and dengue caused 675 and 297 cases of sickness respectively, with no deaths. Alcohol placed on the sick list 193 navy men, 4 of whom died. Heat-stroke overcame 154, a fatal result occurring in only one instance. Typhoid fever attacked 134 of the sailors and marine corps, and caused the death of 11. Pneumonia proved the most deadly disease, for while the number of those who suffered from it was less than from any of the above-mentioned complaints, 117, the deaths reached 15. Eighty-seven men contracted pulmonic tuberculosis, and 8 died. Dysentery cases numbered 68, with no deaths. There were 42 cases of organic heart disease, the mortality from all descriptions of heart affections being 9. Measles and nephritis attacked 37 and 31 men respectively, but caused no mortality. Scarlet fever was responsible for 29 cases of sickness, and caused 2 deaths. Yellow fever was contracted by 8 sailors, half of whom died. There were six cases of smallpox, 4 of which ended fatally. The cases of venereal origin were as follows: Gonorrhœa, 517; primary syphilis, 84; secondary syphilis, 297, the last of which caused 2 deaths. Of other diseases, appendicitis caused 3 deaths; apoplexy, 8; carcinoma, 4; meningitis, 3; miliary tuberculosis, 3; aneurism, 2; asphyxia, 2; kidney disease, 2; hepatitis, 2; septicæmia, 1; poisons, 1; œdema of glottis 1; gastric ulcer, 1, and poisoned wounds, 1. Twenty men met their death by drowning.

The total number of cases under treatment in the various naval hospitals was 3,377, a decrease of 294 as compared with the year 1898. The average number of patients daily under treatment was 328.15, a ratio of 16.32 per 1,000 of force. The deaths numbered 57, and the invalided from service 474, the ratio per 1,000 of cases treated being 16.88 for the former and 140.36 for the latter. The corresponding ratios for the previous year were 19.61 and 200.21 respectively.

In the report upon the United States steamship *Baltimore*, complaint is made as to the situation of the sick bay. The temperature due to its location, directly over the dynamo and steering-engine, is stated to be far too high. It has no water supply and no bath tub, and is separated the whole length of the ship from the dispensary and medical store-room. The light, too, is very deficient. Many of the ships are said to be ventilated in a defective manner, but upon the whole the hygienic arrangements of all the vessels appear to be satisfactory. Some of the special reports are of the greatest possible interest, that contributed by Dr. Corbin J. Decker, surgeon U. S. N., on the establishment of a temporary naval hospital at Taku during recent disturbances in China, being particularly interesting. The Japanese were the first to have a temporary hospital in working order in China. The American hospital, established by the advice of Dr. Decker and placed under his charge, was opened on June 22d, and

closed on July 25th. Its staff performed efficient service, not only to Americans, but to English, Germans, and Russians. The report is well compiled, the several contributions are, as a rule, couched in meritoriously clear and concise language, and show throughout that the health of our sea forces is excellently looked after by our naval medical officers. It is a matter for regret that there are many vacancies—seventeen in the list of assistant surgeons—but the surgeon-general of the navy expresses the hope that these vacancies will be filled as soon as it is generally known that recent legislation gives assistant surgeons in the navy the same rank as assistant surgeons in the army.

THE NEW YORK STATE BOARD OF CHARITIES.

This board, in its thirty-fourth annual report, commences with a defence of its work in the past, and urges, as a reason why the present system of managing and supervising the charities of the State should be continued, the non-partisan policy of the board. The following recommendations for legislation are made:

1. That all the special appropriations for the State institutions within the jurisdiction of the board be included in one bill, with such provisions as will insure in every instance the most careful and economical expenditure of the moneys appropriated, in exact accordance with the intentions of the legislature.

2. That the present site of the State Industrial School in the city of Rochester be sold, and a less costly site be purchased in the country, to which the school can be removed.

3. That the House of Refuge on Randall's Island be also removed to the country, and that the girls' department of the institution be discontinued, the older girls being sent to the new reformatory at Bedford, and the younger to the New York Juvenile Asylum and the New York Catholic Protectory, or like institutions.

Also, that this institution be placed under the rules of the State civil-service commission.

4. That legislation be enacted to prevent the continuance of the fourteen liquor saloons at the gates of the New York State Soldiers' and Sailors' Home, at Bath, which are supported by the patronage of members of the home, and are regarded as a source of demoralization to its discipline.

The recommendations for appropriations to the State institutions within the board's jurisdiction amount to $1,733,755.24; the amount recommended for maintenance being $1,108,800.89, and for extraordinary expenses, mainly for construction work, $624,954.35. A new table of statistics in the report shows the number of inmates in the State institutions, subject to the visitation and inspection of the board, on September 30, 1900, arranged with reference to representation from the various counties of the State.

Out of a total population of 4,250 in eleven such institutions, the counties more largely represented are as follows: New York, 877; Kings, 344; Erie, 299; Monroe, 207; Onondaga, 179; Westchester, 129; Oneida, 112; Rensselaer, 107; Albany, 89; Niagara, 82; St. Lawrence, 81; Orange, 77; Jefferson, 69; Ulster, 67; Steuben, 66; Dutchess and Delaware, 64; Cayuga, 60; Broome, 57; Ontario, 52; Chautauqua and Saratoga, 51.

The report draws attention to the fact that a State hospital for the care of crippled and deformed indigent children has been opened at Tarrytown, and the board has recommended special appropriations for equipment, apparatus, etc., amounting to $4,250 and a maintenance appropriation of $10,000.

The State hospital for the treatment of incipient pulmonary tuberculosis is also specially referred to in the report.

It would appear that, upon the whole, the condition of the charities of New York State is good, and to the board must be accorded great credit for the efficient performance of its trying duties.

RECIPROCITY IN MEDICAL PRACTICE.

No subject connected with medical reform has been discussed so fully within the past few years as that of reciprocity in medical practice. The question has been treated from every conceivable point of view—indeed, many will think that there can be nothing further to say, and that to dwell upon the matter again is but a waste of pen and ink. Interstate medical reciprocity, however, concerns intimately every physician in the United States, and, in a scarcely less degree, the community at large. It is of surpassing importance, and should be—until needful reforms have been introduced—ever kept before the eyes of the medical profession and the general public. There is a saying that "constant dropping will wear away a stone," and upon the same principle, by constantly harping upon the subject, it is to be hoped that physicians may be roused from their lethargy and as a body be brought to appreciate the fact that a uniform raising of the standard of medical education must be of benefit to them, and also that the lay population of the country may become convinced that it will be to their advantage to be enabled to avail themselves of the services of thoroughly competent physicians. The London *Lancet* of January 22d takes as its text two pamphlets written by Dr. Emil Amberg, of Detroit, dealing with interstate reciprocity, and considers the question at some length. A part of the article reads as follows: "The great object in legislation in regard to medical qualifications in all countries is to secure competency in those who receive a license to practise. The only way to attain this security is by regulating the number of bodies having the power to grant qualifications, by depriving them of excuses for competing downward in such work, and by supervising the work they do with competent and independent inspection. The multiplication of medical colleges and corporations, with power to grant licenses beyond all inspections and control by a supervising or central body, is the sure way to lower standards and to retard and degrade medical education, at the expense of the public. This is the unhappy state of matters in the United States,

which constitutes almost the despair of those responsible for American medical education, than whom there are none in the world more anxious to promote the advance of medical science in the interests of the people."

The above is a fair presentation of the conditions prevailing in the United States so far as medical education is concerned. The remedy suggested also would tend to bring about an amelioration of the existing unsatisfactory and anomalous situation.

The truth is that interstate medical reciprocity is at a complete standstill, and will continue to be so until the first necessary steps shall be taken.

That a solution of the difficulty hinges upon a uniform standard of medical education throughout the country is indisputable. Dr. William Warren Potter hits the right nail on the head when he says under the heading "Equality of Standards a Basis for Reciprocity": "The only equitable basis upon which reciprocity can be established that appears both feasible and practicable is that of equality of standards for admission to the study and practice of medicine. This implies an equalization of the preliminary requirements of medical students and a uniformity of applying the tests, a uniform period of collegiate training, including uniformity of methods of teaching, and finally an absolute similarity in the method of conducting State examinations and granting licenses."

The MEDICAL RECORD, March 18, 1899, expressed views of a like nature, phrased thus: "That in no instance should a medical degree be conferred unless the candidate has undergone a course of study, of at least four years, and that the final examination shall be undertaken by an independent and unbiassed board."

The crux of the problem is the manner in which this uniformity is to be compassed. The hope is vain that in a week, or even in a year, such a radical change can be attained. The process of evolution must go on slowly in order to reach sound and practical results. The question then comes up, Can nothing be done at once to initiate the desired reforms? Dr. Emil Amberg thinks this question may be answered in the affirmative, and is of the opinion that the States might be temporarily divided into six groups, taking as a basis the preliminary education, the medical education proper, and the final State examination. Although this plan sounds rather cumbersome, it might, if feasible, be worthy of trial, for the reason, as Dr. Amberg says, "that six groups are preferable to fifty-one or more groups."

The medical profession until recently has shown itself somewhat apathetic and indifferent on the subject. Of late it has awakened to the seriousness of its position, and by its press, medical societies, and individual members, has demonstrated an interest in interstate reciprocity. If it will continue in this path and follow the strenuous example of the Wayne County Medical Society, there can be no doubt that in the course of time the end in view will be gained. In the mean while the medical profession and press must urge the matter by every means in their power, and endeavor to impress upon the non-medical part of the population the great desirability of a uniform high standard of medical education in every State of the country.

News of the Week.

New York Academy of Medicine. — At the next stated meeting, March 21st, 8 P.M., will be considered the modern treatment of gonorrhœa and its complications and sequelæ.

Kentucky State Medical Society.—The forty-sixth annual session of the Kentucky State Medical Society will be held in the city of Louisville, Ky., May 22, 23, and 24, 1901.

Physical Examination before Marriage. — The Indiana Senate has passed a bill for the physical examination of all parties contemplating matrimony. The board to be appointed by the governor is composed of two physicians, two mothers, and one attorney.

Plague at Cape Town.—The progress of the bubonic plague causes deep anxiety and apprehension in Cape Town. The Cape government has decided to remove the people from one-third of the city area and to cleanse it. Every precaution will be taken should the disease spread to the troops.

Famine in China.—The distress from famine in China is increasing with the severity of the weather and more than one hundred thousand persons will perish from cold and hunger. Many stations for free distribution of rice have been established, but they are pitifully insufficient.

Bill for Hospital in New York for Treatment of Nervous and Mental Diseases.—Assemblyman Henry introduced his bill for the establishment of the above hospital, on Thursday, March 7th. The purpose for which the hospital is to be founded was fully explained in the MEDICAL RECORD some weeks ago.

Fined for Practising without a License in Australia.—A man has been fined $250 in Sydney, N. S. W., for representing himself to be a legally qualified medical practitioner and using the title of "doctor." The prosecution was made under the Medical Practitioners Amendment Act which has only just come into force.—*Medical Press.*

Control of Sex.—Dr. Schenk has recently published another book entitled "A Compendium for Determining the Sex of an Unborn Child." He stoutly adheres to his original theory that the determination of sex rest entirely with the mother, and details a number of cases in which he says this theory was demonstrated. He likewise gives records of the diets prescribed, the foods being principally albuminous when males are expected.

Osteopathy Condemned.—A letter to Governor Odell from J. P. Arnold and H. Walters of the Mechane-Newral-Theray School of Trenton, N. J., has aroused additional interest in Assemblyman Seymour's bill regulating and licensing the practice of oste-

opathy. The letter says that osteopathy is only a new way of perverting young women, and an easier way for malpractice. The letter was turned over to Assemblyman Henry, chairman of the public health committee, and he regards the matter as of such seriousness that he is inclined to give another hearing on the bill, and have Messrs. Arnold and Walters come to Albany to speak on the subject.—*New York Sun.*

A Negro Hospital in North Carolina.—Winton-Salem, N. C., is to have a negro hospital. The building is to cost $10,000, of which sum R. J. Reynolds, a white citizen, contributed $5,000, while the negroes of the community raised the remainder. The hospital will be operated in connection with the Slater Industrial School.

The Qualifications of the President of the State Commission in Lunacy.—The Medical Society of the County of New York has entered an earnest protest against the bills before the New York legislature, repealing the existing provision of law which requires the president of the commission to be a physician who has had "five years' actual experience in the care and treatment of the insane, and who has had experience in the management of institutions for the insane."

JOHN VAN DOREN YOUNG, *Secretary.*

Candidates for Appointment as Dental Surgeons in United States Army will be examined in the following named branches: Anatomy, physiology, histology, physics, chemistry, metallurgy, dental anatomy and physiology, dental materia medica and therapeutics, dental pathology and bacteriology, orthodontia, oral surgery, operative dentistry (theoretical), prosthetic dentistry (theoretical), operative dentistry (practical), prosthetic dentistry (practical).

An average of seventy-five per cent. will be required in each subject for theoretical examination, and eighty-five per cent. in the practical examinations.

College of Physicians of Philadelphia.—At a stated meeting held March 7th, Dr. W. W. Keen demonstrated "Bloom's Apparatus for Artificial Respiration." It consists of a bellows connected by a rubber tube with an intubation-apparatus for introduction into the larynx, through which air can be introduced into the lungs, and from which it can escape. If it be deemed desirable, the vapor of an anæsthetic can be introduced into the air passages in the same way. Dr. George W. Crile, of Cleveland, Ohio, read by invitation a paper entitled "Experimental Research into Surgical Shock and Collapse," with stereopticon illustrations. As a result of experiments on dogs, he had found that little or no shock followed even severe manipulation of skin, muscles, and bone, while such shock followed injuries of nerves, of the peritoneum, violent traction of the tongue, and especially manipulations about the larynx. He pointed out that when death results suddenly from drowning, it is not then due to asphyxia, which is a slow process, but to inhibition of the action of the heart, from the entrance of water into the larynx unclosed by the epiglottis. Collapse was attributed especially to failure in the vasomotor mechanism, in consequence of which the blood was not propelled from the periphery and, particularly, from the veins to the heart. When such a condition arose, no remedy was known that was capable of correcting it. The importance of prophylactic measures was thus obviously urgent.

The Western Ophthalmologic and Oto-Laryngologic Association will meet in its next annual session in Cincinnati, Ohio, April 11th and 12th. Dr. C. R. Holmes, of Cincinnati, is chairman of the local committee of arrangements. Dr. M. A. Goldstein, of St. Louis, is the president, and Dr. W. L. Ballenger, of Chicago, is the secretary.

A Believer in Dowie Refuses Physician's Aid for her Dying Husband.—In Chicago a man named Rades was reported recently to be dying of rheumatism of the heart, and his wife, who is a follower of Dowie, would allow no physician to visit him. The police when appealed to visited the house with two physicians, but upon being refused admittance declined to force an entrance, declaring that such action would be against the law unless authorized by a member of the family. The sick man himself was stated not to be a believer in Dowie, and his friends asserted that if he had not been delirious he would have demanded the services of a physician.

Annual Meeting of the Association of Medical Officers of the Army and Navy of the Confederacy.—The Association of Medical Officers of the Army and Navy of the Confederacy will convene in Memphis, Tenn., May 28–30, 1901, during the meeting of the Confederate Reunion. All surgeons, assistant surgeons, acting assistant surgeons, or contract physicians and hospital stewards, in the army and navy of the Confederate States, and all regular physicians who served honorably in any capacity in the Confederate States army and navy, and all regular physicians who are sons of Confederate veterans, are eligible to membership.

Druggists' Insurance against the Results of Carelessness.—It is said that about a thousand druggists of this city and vicinity are insured in several fidelity and casualty companies against damages arising from errors in compounding prescriptions. The idea of insuring druggists against loss from their own mistakes originated in the belief of a number of leading pharmacists that they were the victims of a gang of rogues who made a practice of pretending that wrong medicines had been given to some member of their families, sometimes with serious results. The gang was partly broken up by the fidelity company which first assumed the responsibility of protecting druggists. The yearly premium for a protecting policy varies from $15 to $25.

An International Congress of Nurses will be held in Buffalo next September, during the time of the Pan-American Exposition, with the object of cementing and strengthening the national and international organizations which the nurses of this country, Great

Britain and the colonies, Denmark, and Holland, have established in the last few years. All of these countries have now national organizations of nurses, pledged to uphold the honor and best interests of their profession, and to work for a steadily advancing educational standard and ethical development. The nurses of the English-speaking countries have also in view the attainment of State examination and registration.

Academy of Medicine.—In the section of obstetrics and gynæcology, Dr. Abram Brothers has been elected *Chairman* and Dr. Sara Welt-Kakels *Secretary*.

Physician Kills Wife and Commits Suicide.—Dr. W. F. Aiken, of Savannah, Ga., an eye and ear specialist, shot and killed his wife on February 27th, and then shot and killed himself. Dr. Aiken, who was a graduate of Yale, was born in New York, and at one time was in the city health department. He was a man of considerable literary and scientific attainments, and is said to have been very successful in practice in Savannah. Dr. Aiken was thirty-six years of age.

Alcohol as a Food.—Alcohol as a food was condemned at Friday's, March 1st, session of the superintendent's department of the National Educational Association. On this subject and the report submitted by a committee of seven appointed a year ago to investigate the value of alcohol as a food, a lively debate was expected. The report of the committee, however, simply stated that "no authority has been found to maintain that alcohol is a food," and recommended literature discussing the subject. It was adopted with little discussion, this action being regarded as a victory for the conservative element among the educators. School children, accordingly, will simply be told that alcohol is injurious, and no special course of instruction on the human system will be given.—*Tribune.*

Pathological Society of Philadelphia.—At a stated meeting held February 28th, Drs. Richard H. Harte and Robert N. Willson, Jr., presented a communication entitled "Primary Carcinoma Limited to the Vermiform Appendix." The patient was a young woman, twenty-four years old, who had presented symptoms of appendicitis. When the appendix was removed, its lumen was found almost completely obliterated, but the presence of a new growth was disclosed only on histological examination. Drs. D. J. McCarthy and M. P. Ravenel presented a communication entitled "Melanosis of the Cerebro-spinal Membranes in a Case of Rabies." The specimen was obtained from a cow, the pia being deeply pigmented, both upon the spinal cord and in part also upon the brain. Dr. William S. Wadsworth read a paper entitled "Injuries to the Brain," in which he pointed out many of the circumstances that contribute indirectly to lesions of the brain in connection with traumatism. Dr. M. B. Hartzell read a communication entitled "Lenticular Cancer of the Skin." Following an operation for excision of an ulcerated lesion upon the sole of the foot, thought to be epitheliomatous, numerous small nodules appeared in the skin of the leg. These, on histological examination, were found to present appearances strongly suggestive of carcinoma, yet not wholly unlike sarcoma. Dr. John B. Roberts read a paper entitled "Multiple Tumors of the Sciatic Nerve." The growths were probably fibromata, and were present in considerable number.

The Tenement-House Commission.—The tenement-house commission declares that in the building of nearly all the recently constructed tenement houses in New York the law has been violated. There is little hope of tuberculosis being stamped out, or even checked, if the building laws are not rigidly enforced.

The German Hospital, New York.—In the annual report of the trustees of the German Hospital, just published, it is shown that, among the 22,595 patients treated in 1900, bakers were most numerous. There were 134 of them, also 110 clerks, 72 drivers, 67 butchers, and 70 waiters.

Charity Workers Hopeful.—The officers and members of the various charitable organizations in New York City, who have been opposing Governor Odell's plan to take the charities of the State from the management of an independent board and place them in control of a political party, believe now that their efforts will be successful, and that Governor Odell will abandon his scheme.

His Leg Cut Off Six Times.—*The Kansas City Journal* is responsible for the following veracious and affecting tale: Edward Conrad, a railroad gateman of Allegheny, Pa., suffered an injury some years ago which made it necessary to amputate one of his legs. Since then he has had five accidents, in each of which his artificial leg, which was provided him in lieu of the one he lost, was cut off.

Died at the Age of One Hundred and Seventeen Years.—George Peter Newkirk, a negro, known as "Old George Pete," died at his home in Hurley, N. Y., February 25th, at the extraordinary age of one hundred and seventeen years. "George Pete" had been a familiar figure to generations of prominent men and women whose early lives were passed in Ulster County. He was born and brought up a slave in the Newkirk family, and continued to reside with some member of that family all his life.

Anti-Christian Science Bill. — Missouri's house passed the measure prohibiting unlicensed healing. The Missouri medical bill, which has been so objectionable to Christian scientists because it prohibited them from attempting to heal the sick without a license from the State board of health, passed the house of representatives March 2d, by a vote of eighty-four to forty-two. The bill got seventy-seven votes on engrossment two weeks ago. The action was a great surprise to the Christian scientists, who had brought all their forces to bear to defeat the bill. The same bill, introduced in the senate, was engrossed there on February 27th, and the indications are that the senate will pass it by a good vote. The bill prohibits persons not now registered as physicians from practising medicine or surgery in any of its departments or from professing to cure or attempting to treat the sick, except when healers are

examined as to their fitness to engage in such practice. The bill does not repeal the law allowing osteopaths to practise, but it applies to all others who heal the sick for pay. Examinations are conducted and licenses issued by the State board of health. The bill allows persons who have no licenses to treat cases of illness in case of emergency, but they can make no charges for such services.

Sanitation in Pekin.—The London *Morning Post* has received a despatch from Pekin, to the effect that the foreign administrators of that city are taking precautionary measures against epidemics in the spring. The same despatch states that the Americans are more careless in this respect than the other nationalities. The sanitary regulations being carried out by the British are said considerably to surprise the Chinese.

War on Rats at Cardiff.—Cardiff, in Wales, a town of very considerable size and a seaport of world-wide fame, has been attacked by plague. Up to the present but two or three cases have developed, but as may be well imagined even these few have caused widespread alarm. A vigorous crusade against rats has been undertaken, as it has been clearly proved that some rats found dead in Cardiff had died of the plague. At Cape Town, where plague-stricken rats are also reported to have been found, a reward of six cents per head of these vermin has been offered, and a special staff is engaged in exterminating them in the docks.

Medical Practitioners in Austria.—The government return for medical practitioners actually engaged in the profession is 10,576; of these, 3,054 are in Lower Austria, 369 in Upper Austria, 114 in Salzburg, 674 in Styria, 141 in Carinthia, 99 in Craniola, 331 in Cortland, 548 in Tyrol and Voraelberg, 2,563 in Bohemia, 881 in Moravia, 225 in Silesia, 1,313 in Galicia, 134 in Bucowina, 131 in Dalmatia, while in Bosnia and Herzegovina there are only 97 in practice. Vienna itself has 2,442; Trieste, 185; Prague, 450; Brünn, 162; Grätz, 258; Innsbruck, 61, etc. It will be seen from these figures that the capital towns contain most of the medical men in practice. The government is dissatisfied with this distribution, and desires them to go farther into the country.—*Medical Press.*

The London School Board and the Coal-Smoke Nuisance.—That excellent body, says the London *Pall Mall Gazette*, the Coal Smoke Abatement Society, has addressed a letter to the London school board, urging it to look after its grates and stoves. A good example set by so influential an institution would, in the opinion of the C. S. A. S., have a most salutary effect. The suggestion is, therefore, that, when occasion arises, the board should specify some form of apparatus that will materially reduce the evil of an imperfect combustion. The board might possibly retort that the C. S. A. S. should give point to its gentle admonition by mentioning some particular stove or stoves. The Coal Smoke Abatement Society has at any rate justified its existence by jogging up the school board and other public organizations, which, as it cautiously reminds them, are amenable to the law for allowing their chimneys to emit a black and evil-smelling cloud. Its crusade against domestic chimneys is a more difficult undertaking, and it falls back upon that vague phrase, "the gradual education of public opinion." Very gradual, we fear.

The "Practitioner" on the South African Hospital Commission.—The London *Practitioner* for February, which has always been, of the British medical journals, the most clamorous for reform in the army medical service, discourses as follows on the result of the South African hospital commission: "The report of the hospital commission is, in its general tenor, exactly such as had been foreseen by all who knew anything of the Royal Army Medical Corps and the conditions under which it had to work in South Africa. The report is by no means a mere 'whitewashing'; it is a decisive acquittal on nearly all the counts of Mr. Burdett-Coutts' sweeping indictment. No finer tribute to the general efficiency, as well as the heroism and devotion, of the medical officers of the army has ever been paid; but the commission lays its fingers on many defects. It would be wonderful, indeed, if in a large body of men working under such terrible stress, mental and physical, as was the lot of the R. A. M. C. in South Africa, there had not been found some who failed to come up to the highest ideal of the medical profession. All the serious defects, however, pointed out by the commissioners, are clearly shown to be due, not so much to the shortcomings of the R. A. M. C., as to those of the war office. For years it has been predicted by *The Practitioner* and other medical journals that the insensate folly of the military pedants, who have so persistently opposed every attempt to place the army medical service on a sound and efficient footing, would lead to a breakdown in case of war. Now that the responsibility for the grievous suffering which our troops have undergone as a consequence of this policy has been publicly placed on the right shoulders, there is a prospect that the evil tradition of war-office perversity and obstructiveness may be swept away and the whole organization of the Royal Army Medical Corps thoroughly reformed."

Proposed Law for the Prevention of Malaria in Italy.—The text of the bill as drawn up by Celli and others has been published. It consists of five articles, the first of which provides for the official declaration of affected zones, and the second for the gratuitous distribution of quinine to the poor by municipal authorities, and the taxation of property for the purpose of raising the necessary funds. Article 3 makes it incumbent upon the government department or government contractor responsible for the execution of any public works which give rise to the occurrence of malarial fevers to supply quinine gratuitously, and requires that if any person dies or becomes permanently disabled from malaria while employed on such works, the same indemnity must be paid as that established for persons under the employers' liability act of 1893. Article 4 enjoins protection against the

entrance of insects to all homes within the malarial zone, inhabited by persons employed in the public service and on public works, from the beginning of June to the end of December, and offers rewards not exceeding 1,000 lire ($200) to proprietors and manufacturers who do the like for the houses of their employés and of the peasants. Article 5 empowers the government to take whatever further measures may seem necessary for the carrying out of the provisions of the law, after such measures have been approved by the Superior Council of Sanitation and by the Council of State.—*Lancet.*

Attendance at German Universities.—*The Lancet* says: "The number of students registered at the German universities this winter is 34,363, as compared with 27,784 in the winter of 1894–95, so that an increase of 20 per cent. has taken place during the past six years. The attendance of students at the various universities is as follows: 6,673 in Berlin, 4,184 in Munich, 3,584 in Leipsic, 1,917 in Bonn, 1,731 in Halle, 1,638 in Breslau, 1,350 in Tübingen, 1,317 in Göttingen, 1,280 in Heidelberg, 1,218 in Freiburg, 1,264 in Würzburg, 1,132 in Strasburg, 1,053 in Marburg, 967 in Erlangen, 874 in Königsberg, 847 in Giessen, 780 in Kiel, 733 in Munster, 726 in Greifswald, 681 in Jena, and 512 in Rostock. As regards attendance in the various faculties, there are 2,327 students of Protestant theology, 1,584 of Roman Catholic theology, 10,511 of law and national economy, 7,113 of medicine, 5,200 of philosophy and history, 4,722 of mathematics and natural science, 1,157 of pharmacy, 1,512 of agriculture, and 448 of dental surgery. Moreover, at the University of Giessen there are 126 students of veterinary medicine, but in other parts of Germany veterinary medicine is taught at special colleges not belonging to universities. These figures, compared with those of the previous year, show that the students of Protestant theology have decreased by 86, and the students of medicine by 430. The students of other branches have increased considerably, especially the students of law, where the increase has been 47 per cent. during the past ten years. At the University of Berlin there are 366 students registered in the faculty of theology, 2,359 in the faculty of jurisprudence, 1,312 in the faculty of medicine, and 2,636 in the faculty of philosophy. With respect to nationality, 4,679 students come from Prussia, 994 from the other states of the empire, and 714 from foreign countries. Of foreigners of European origin the majority (318) come from Russia, 112 from Austria, 88 from Switzerland, 62 from Hungary, 32 from Great Britain and Ireland, 22 from Italy, 20 from France, 20 from Roumania, 17 from Turkey, 17 from Servia, 16 from Bulgaria, 15 from Sweden, 15 from Greece, 12 from the Netherlands, 11 from Luxembourg, 5 from Belgium, 4 from Spain, 3 from Denmark, and 1 from Portugal. Of foreign students from distant parts of the world, 114 come from America, 62 from Asia, 3 from Africa, and 1 from Australia. Berlin is, therefore, in reality cosmopolitan. In addition to the duly registered students, there are 5,466 persons who are entitled to attend the lectures there; for instance, the students of the technical and other academies and others to whom this right has been granted by a special decree of the senate of the university. The number of female students is 439."

Death Rate of Montreal for 1900.—There were 7,351 deaths in Montreal in the year 1900. This was the largest number which has been recorded since 1885, when 7,825 deaths occurred; but since that year the city has immensely increased in population. In 1885 the death rate per 1,000 was 26.91, and in 1900 it was 25.47. In other recent years the rate was as follows: 1894, 27.27; 1895, 24.81; 1896, 21.92; 1897, 22.48; 1898, 20.66, and 1899, 24.51.

Mr. Reginald Harrison, of London, the famous genito-urinary surgeon who is on a short pleasure visit to America, arrived in New York on Sunday, March 10th, *en route* for Palm Beach, Fla. During his sojourn in this city he was the guest of Dr. Frederic S. Dennis, who entertained him at dinner on Tuesday evening. Dr. Samuel Alexander gave him a luncheon on Wednesday at the University Club, which was largely attended by prominent surgeons and other distinguished guests. In the afternoon, by invitation of Dr. Alexander, he lectured at the Cornell Medical College on some practical points in prostatic disease and tension of the kidney, before a representative audience of hospital surgeons and students. He intends to return home March 30th.

A Very Young Mother.—Dr. R. R. Thompson, of Kingston, N. Y., writes: "March 5th I attended a case of labor in which the mother of the child was thirteen years of age on February 4, 1901. This made the little mother but thirteen years one month and one day old. The infant was an eight months' child. The labor extended altogether over a period of about four hours, and was normal in every respect. There was not the slightest laceration of the perineum. The child weighed six pounds. The girl had menstruated only two or three times."

Medical Society of the Missouri Valley.—The thirteenth semi-annual meeting of this society will be held at Omaha, Neb., March 21, 1901.

Monument to Professor Ollier.—A committee has been formed in America, similar to those formed in several European countries, for the purpose of receiving subscriptions for a monument commemorative of the distinguished scientific services of Professor Leopold Ollier. The municipality of the city of Lyons has dedicated an open space adjacent to the quarters of the various academic faculties, on the border of the Rhone, named in his honor "Place Leopold Ollier." The committee hopes to raise not less than $1,000 as a testimonial from the profession of America. Checks should be forwarded to W. W. Keen, 1729 Chestnut street, Philadelphia, Pa., and at as early a date as possible.

A Tribute to the Efficacy of Female Nursing.—Perhaps, says the *The Hospital Nursing Mirror*, the most interesting feature to nurses in the letter in the *Times*, February 13th, of Mr. Burdett-Coutts, M.P.,

on the South African hospital commission report, is his reference to the nursing at the Volks Hospital, Bloemfontein. He says: "The Volks Hospital, Bloemfontein, was the only one in which the patients were properly nursed by female nurses. Its principal doctor was Dr. Keller, formerly mayor of Bloemfontein; its matron, Miss Maud Young, a strong, able, and efficient superintendent, who had a staff of eight nurses under her. There was no royal army medical corps doctor or trained orderly in the hospital. The equipment was plain, simple, convenient, but in no way elaborate or luxurious. As admitted by the report with regard to the private hospitals, the serious cases gravitated to this one also. Its proportion of admitted convalescents would be *nil*. It had to deal with the epidemic under the same conditions of pressure, climate, provisions, water, and other matters, as the rest of the hospitals around it; but owing to the untiring energy and devotion of its matron and female staff it was properly nursed. What was the result? The general enteric mortality was twenty-one per cent. The same mortality in the Volks Hospital was 7.75. This is the best practical proof that could be given of the value of female nursing of sick and wounded soldiers."

Plague-Infected Rats on Ship.—Some anxiety was felt lately at Hamburg when the port sanitary authorities found many dead rats on board the steamer *Pergamon*, and bacteriological examination showed that the animals had suffered from plague. The steamer and the cargo were therefore thoroughly disinfected, and everything that the rats had gnawed was burned by the fire brigade. No case of plague has subsequently occurred among the crew.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for week ending March 9, 1901. Assistant Surgeon O. M. Eakins detached from the *Ajax* when put out of commission and ordered home to wait orders. Surgeon F. J. B. Corderio detached from the *New Orleans* and ordered to the *Buffalo*. Passed Assistant Surgeon R'Spear detached from the *Buffalo* and ordered to the *Isla de Luzon*. Passed Assistant Surgeon R. M. Kennedy detached from the *Newark* and ordered to the *Bennington*. Assistant Surgeon J. J. Snyder detached from *Isla de Cuba* and ordered to duty with a detachment of marines at Pollock, P. I. Assistant Surgeon M. V. Stone detached from the *Isla de Luzon* and ordered to the *Buffalo*. Assistant Surgeon J. H. Payne, Jr., detached from duty at Pollock, P. I., and ordered to the *Isla de Cuba*. Assistant Surgeon E. O. Huntington detached from the *Bennington* and ordered to the *Newark*.

Tragedy in a Paris Sanatorium.—The "Villa de la Gulle," a sanatorium kept by a Paris doctor in the Route de Versailles, has been the scene of a tragic shooting affair. Among the boarders inhabiting the villa were a Monsieur Henri Bellencontre and Monsieur A. Yanés. The latter was suffering from the persecution mania, and had consulted several physicians, who suggested only quietude and agreeable surroundings, both of which were to be sought in the villa in question. It appears that M. Yanés one evening, while in a restless mood, entered the library where some boarders were reading and chatting. M. Bellencontre rose to bid him good evening and offer his chair, whereupon M. Yanés produced a revolver from his pocket and shot, afterward turning the barrel toward himself and firing.

Obituary Notes.—Dr. Robert Stone, son of the late Joel Stone, died at the Hotel San Remo on March 7th, aged sixty-four years. Dr. Stone was born in Barclay Street, New York City, studied in Frankfort, Germany, and in Paris, and was graduated from the College of Physicians and Surgeons, New York. He practised medicine in New Haven and later in Irvington, Tarrytown, and Yonkers, and retired fifteen years ago.

Dr. John Dean Ross died at Williamsburg, Pa., on March 5th, at the age of ninety-five years. He was graduated from the medical department of the University of Pennsylvania in 1832. He founded and was the first president of the Blair County Medical Society.

Progress of Medical Science.

New York Medical Journal, March 9, 1901.

The Surgery of the Turbinal Bodies with a New Method of Operating.—J. E. Boylan advocates, in dealing with turbinal redundancy, the judicious amputation of the offending portions rather than their reduction with the cautery. He concludes from a study of over one hundred cases: (1) That turbinal hypertrophy is usually greatest at the extremities of the bones, rather than in the middle; (2) that the relief of obstruction is accomplished more certainly and accurately by ablation than by cauterization; (3) that while venous dilatation is greatest at the posterior extremities, obstruction is rarely due to hypertrophy at this point alone. For the removal of the offending tissue he uses either the saw or scissors, or both, or the cold wire snare. In order to prevent the latter from slipping he has frequently fixed the end of the loop by burying the point of a fine tenaculum (the hook of which was bent so as to be somewhat at an acute angle) into the lower margin of the turbinated body at the point of operation, carrying the loop over the handle into the meatus and adjusting it so that it passed behind and was held in place by the back of the hook. In forty-two cases it was possible to examine the nose one year after operation, and in no instance was there a complaint of discomfort attributable to the operation—a condition of affairs which the author was not able to obtain from the use of the cautery.

Blood in the Urine and the Diagnosis of its Source.—J. Wiener, Jr., does not believe that reliance is to be placed wholly on the cystoscope and the ureteral catheter, to the entire exclusion of other and older plans; for these two diagnostic methods are not always applicable. In the presence of hæmaturia, we are to ask ourselves as to the source and the cause of the bleeding. The diagnosis may be made from the history of the case, the examination of the urine, and the examination of all the organs. History should include inquiries into the family history, previous personal history, age, time at which the blood appears in the urinary flow, frequency and duration of attacks, and the effects of exercise or of complete rest in the course of an attack. The urine should be examined macroscopically, microscopically, and chemically. Other organs, as the heart, lungs, spleen, etc., should all be carefully examined, for their condition may suggest the origin of the hæmaturia. The author then discusses the peculiarities of hemorrhage from the urethra, prostate, bladder, and kidney, respectively.

The Radical Treatment of Malignant Disease of the Larynx.—By Ernest Waggett. The author takes issue with the statements of J. N. Mackenzie (see *New York Medical Journal*, September 8, 1900) on the advisability of early total extirpation of the entire organ, with its tributary lymphatics and glands. He claims that Mackenzie has not done justice to the most recent statistics on thyre-

otomy, and that the latter operation in the last few years has won for itself a deserving place in the treatment of malignant laryngeal tumors. Waggett's paper is largely statistical and does not well lend itself to abstracting. He claims that the figures of thyreotomy of these later years are infinitely superior to those of total extirpation, and that, as at present practised by English surgeons, the former is yielding brilliant results.

Resorcin as a Preservative for Suprarenal Solution.—S. Oppenheimer recommends the addition of sixty grains of desiccated suprarenal extract to one ounce of a one-per-cent. resorcin solution in sterile water. The preparation is free from septic properties and the vasomotor properties of the extract are in nowise diminished. The solution has been kept for six months without impairment.

Ichthyol in the Treatment of Deep-Seated Inflammations.—By W. T. Slevin. The following formula is given: Ichthyol, gr. xlv.; lead iodide, gr. xlv.; ammonium chloride, gr. x., and petrolatum to make one ounce. This preparation is to be rubbed on. Clinical histories are given illustrating its efficacy in erysipelas, quinsy, and bronchopneumonia.

The Specific Treatment of Acute Dysentery.—By W. J. Cruikshank.

The Pathology of Intra-uterine Death.—By Neil McPhatter.

Philadelphia Medical Journal, March 9, 1901.

Operative Treatment of Tuberculous Lymphomata of the Neck.—Prescott Le Breton quotes Horace Grant's opinions concerning this subject: Although in the removal of the lymphatics there is a loss of protection for a time, the remaining glands and newly formed lymphatic channels soon perform an extra duty, just as one kidney will do the work of two, or as one part of the brain will do the work of a part previously excised. The difficulties of complete removal in competent hands are never insurmountable. Dissemination of tubercle bacilli may be prevented by careful dissection and cleanliness during the operation. The writer adds that undoubtedly the general trend of opinion among surgeons in this country is toward radical operation in all cases that have withstood medical treatment. Watson Cheyne gives the most practical classification according to clinical characteristics and indications for treatment: (1) Cases in which the glands remain hard, small, and movable, with no marked tendency to softening or matting together. As long as the glands are quiescent they may be left alone, and medical treatment alone instituted. (2) Cases in which the glands enlarge steadily, or at intervals, till the whole side of the neck is involved. This condition demands complete excision. (3) Cases in which the inflammation is very active and suppuration takes place. Excision, with removal of capsules, fat, and neighboring glands is indicated. (4) Cases in which there are unopened abscesses; if only one or two glands enlarge and suppurate, by making an oval incision over the mass and dissecting outside the abscess, one may often enucleate the abscess and glands *in toto*. If the abscess is accidentally opened while being dissected, the pus should be washed away immediately. When the abscess has broken through the deep fascia and undermined the skin, it is sometimes wise to incise and drain three to four weeks and then operate, rather than excise the thin skin over the abscess and leave a large scar that may stretch. (5) A series of long-standing cases in which ulcers and sinuses remain with remnants of broken-down tuberculous tissues and glands at the bottom; the treatment is either excision or scraping, with the application of iodoform or carbolic acid. It is most important in operating to go wide of the disease, as in operating upon malignant growths. An important adjunct to the treatment is the removal of adenoids and hypertrophied tonsils, and the care of carious teeth. Eczema of the scalp, rhinitis, and otitis demand attention.

Albuminous Nutrition and Nutritious Albumen.—Albert Bernheim, in reviewing the work that has been done on this subject, gives a *résumé* of the nature and use of a prepared food which consists of nutritious albumen: (1) It is a powder of almost chemically pure albumen of animal and vegetable origin, in the average proportion in which the daily food is usually mixed. (2) It is slightly brownish, odorless, and tasteless. (3) It is sterile and can be kept for any length of time in any climate without deterioration. (4) The plain preparation is not soluble in water, but is readily accessible to the secretory juices of the alimentary apparatus. The iron mixture is soluble. (5) It is resorbable to an extent of more than ninety per cent. of its weight taken into the body. (6) It can be eaten as food by itself, or readily be added and mixed with any other food without changing taste or flavor of the food. (7) It is an exceedingly cheap proteid food for the sick as well as for the healthy person. It is ideal nourishment for the soldier and traveller. (8) Its bulk is small, so it yields good results in malnutrition of the insane, anæmics, consumptives, etc.; in diabetes and gout. (9) It loses none of its good qualities, as it is insoluble in water. (10) It will and must become one of the foods of the future.

On the Necessity for the Organization of Bacteriological Commissions for the Study and Investigation of Quarantinable Diseases, under the Formation and Control of the Governing Authorities of the Countries Interested; an Absolute Necessity for the Scientific Management and Betterment of Maritime Hygiene and Quarantine.—By Henry R. Horlbeck.

The Actions of Morphine upon Metabolism, with Especial Reference to "Internal Secretion" and its Bearing upon Toxicology.—By Edward T. Reichert.

A Skiagraph of Bennett's Fracture of the Metacarpal Bone of the Thumb or "Stave of the Thumb."—By John B. Roberts.

A Cast and Skiagraph of the So-Called Smith's Fracture of the Lower End of the Radius.—By John B. Roberts.

The Function and Distribution of Combined Hydrochloric Acid in Proteolytic Digestion.—By A. E. Austin.

False Pregnancy (Pseudocyesis) and Myxœdema.—By Edward P. Davis.

Paresis Simulating Brain Tumor.—By Wharton Sinkler.

Boston Medical and Surgical Journal, March 7, 1901.

The Interpretation of Bacteriological Findings in Diphtheria Diagnosis.—Hibbert Winslow Hill says that the relation of the board of health to the patient showing a positive culture is comparatively simple. It does not take the position that a sick person is necessarily suffering from the disease of diphtheria simply because a positive culture has been obtained, although this is usually true. The board does insist, however, that such a person is a nucleus from which the bacilli may be spread, and remains such until the bacilli disappear. The patient may be harmless, despite the positive culture, if the bacilli in his nose or throat are not actively producing toxins. But it being impossible to apply the methods for determining that the bacilli fail to produce toxins, in many cases, the board feels justified in assuming that those cases are virulent, on the strength of very much evidence which shows that the error involved in this assumption is small.

Case of Recovery after Operation for Acute Pancreatitis.—J. C. Munro reports a case in which the pancreas was broken up and the wound drained. The patient was very ill, and a month later the wound had to be explored and more diseased matter resembling pea soup removed. Four days later the writer opened through the sinus into another cavity that went up behind the lesser peritoneal cavity. At the lowermost part of all these cavities a free opening was made in the loin. The patient continued to discharge grayish material for some time, but finally the sinus closed, and she has been well ever since, except for one or two slight gall-stone attacks. She has gained in weight and apparently digests everything.

Destruction of the Left Eye and Frontal Lobe of Brain from a Shotgun Explosion.—Edward Swasey reports the case of a boy aged sixteen years, whose whole frontal lobe was practically destroyed as the result of the explosion of his gun. The breech-pin and screw were embedded in the wound made and had to be removed, and were found to be very rusty and dirty. Meningeal hemorrhage, collapse, or meningitis were feared, but for four weeks after the operation the boy led a very comfortable existence, and then died suddenly.

Acute Pancreatitis.—M. H. Richardson thinks that in all obscure inflammations of the epigastrium, attended by acute sudden pain, we ought to explore. If we cannot do anything else, we can at least drain. From the nature of things, we probably cannot save many cases. The diagnosis of these obscure lesions is practically impossible unless time is taken for study, which the imperative call for operation forbids. In all of the cases which the author has seen in which the diagnosis of pancreatitis was confirmed, death has followed.

Cancer of the Extremity of the Common Bile Duct.—By Robert J. Edes.

Convulsions in Children.—By William N. Bullard.

Medical News, March 9, 1901.

The Prevention of Insanity.—Henry Waldo Coe states that not less than fifty per cent. of the insane should never have been born, and that for this mistake physicians are to a certain extent responsible. The author sees no serious objection to the marriage of a woman who has recovered from insanity, if the dangers of the puerperium are eliminated and the prospects of progeny done away with through the removal of the ovaries, the future husband being informed of the true state of affairs. It is a rule to be invariably advocated that, when insanity is in a family, inter-

marriage should not be contracted. After marriage has taken place, the advice that no children shall be born is good but not always effective. During pregnancy and lactation the mother must be treated with the greatest gentleness. Sleep is the greatest foe which insanity has, as syphilis and heredity are its greatest friends. The administration of drugs should be most careful. The food for the growing child of neurotic taint should be carefully selected and prepared. Masturbation in a boy should be guarded against. The schooling of the child should be carefully planned. In all things the child should have his life shaped so that he is to be a man in the middle of the marching column—neither at the head nor at the foot. As a business man, he should enjoy an out-of-door life as much as possible. The surgical defects of patients who have possibilities for mental trouble should have the careful attention of our surgeons. Syphilis must be treated. All epilepsies demand closest attention. Hysteria and neurasthenia and kindred states must not be overlooked. Alcoholism and the gambling habit must be avoided.

The Present Status of the Subarachnoidean Injection of Cocaine for Anæsthesia (Corning-Bier Method).—John S. Miller declares that the enthusiasm of the surgeon must be tempered by the conscientious observance of the most minute details. To be misled by the *furor* is both reprehensible and sad. Cases should be carefully selected, and this variety of anæsthesia should be used only when ether and chloroform are contraindicated. Cocaine is at times very perverse in its physiological effects. A decided advantage over general anæsthesia is that the respiratory, cardiac, and renal organs are not so seriously disturbed as by the inhalation method. The patient can also confer with the surgeon during the operation in case a modification of the original plan must be made. Among the disadvantages are almost uncontrollable headache, lasting sometimes a week, nausea, vomiting, vertigo, cyanosis, elevated temperature, weakness, and relaxation of the sphincters sometimes lasting several days. Psychological disturbance may be extreme. On the whole, the reports of American operators are more favorable than those of our European colleagues. The matter of preparing the solution has not been settled. The writer believes that there is a medico-legal element in these experiments. The absolute consent of patient and family would be advisable before operation.

The Intravesical Evidences of Perivesical Inflammatory Processes in the Female.—By Frederic Bierhoff.

The Tonometer and its Value in Determining Arterial Tension.—By Henry L. K. Shaw.

Our Duties Toward the Consumptive Poor.—By S. A. Knopf.

Journal of the American Medical Ass'n, March 9, 1901.

Municipal Sanitation.—Walter Wyman declares that in municipal sanitation the chief attention should be centered upon the worst parts of the city. The sewerage, paving, light, and ventilation should be carefully considered. Good sanitary environment, enhancing the general health, is the best means of eliminating contagious diseases. Among the sanitarians we need good lawyers and men of extreme wealth. The average doctor or "sanitarian" is as a child in these matters. Sanitary tenements are necessary. As to the appointment of health officers, they should not be too frequently subject to political change and they should command the respect and receive the support of the practitioners of medicine whose influence in this direction is all-powerful. The sanitation of seaport cities which habitually breed yellow fever is being seriously considered. There should be international agreement in sanitation. There might be a convention composed of public sanitarians, civil engineers, and financiers, whose duty it should be to prepare a treaty providing for the examination of the chief yellow-fever ports by a commission representing the nations concerned.

Acute Temporary Dilatation of the Heart Accompanying Thermic Fever.—C. F. Close reports two cases. The first was that of a boy aged seventeen years, who had to work where the heat was very intense. He had a sunstroke with the usual symptoms. The heart was found to be greatly enlarged in all its dimensions, but especially to the right, reaching to the right border of the sternum. Under the ordinary treatment—recumbent position with elevation of, and ice compressor to, the head; cathartics, etc.—he recovered rapidly, and ten days later the heart had subsided to its normal boundaries. The second patient was a woman aged twenty-three years. She was overcome by heat and presented the same symptoms as the first patient. The heart was increased in size, chiefly to the right. In two weeks it was again normal. The writer believes the cause of this phenomenon to be in the nervous system—a part of the general muscular relaxation and the result of profound shock. There is also a general venous congestion which especially overtaxes the right ventricle.

Rupture of the Membrana Tympani from Indirect Violence, with Concussion of the Labyrinth and Complete Deafness.—Richmond McKinney describes this case, which he saw on the day following the accident. The patient had been struck on the right side of the head with a wagon-wheel spoke and had lain senseless for half an hour. On examination, the entire drum membrane of the affected ear, excepting the membrana flaccida, was found congested. The handle of the malleus was also congested. In the posterior half of the membrane was a perforation—perfectly straight and not gaping—running for almost two-thirds of its diameter. The patient was completely deaf. In a few days the perforation had entirely healed. In about three weeks the patient had returned to work, with a practically perfect drum, but was still stone deaf in the affected ear. For several days after the accident the patient had spit blood at intervals.

Hereditary Subnormal Color Perception.—F. Savary Pearce reports a case of this kind. The patient, a man, suffered from hypochondriasis and recurrent melancholy. He was very intelligent. He had arteriosclerosis; there was present also a chronic cystitis. He could not distinguish red from green. His mental fabric was always queer, and one year after examination he was committed to an asylum for the insane. Antopsy showed an absence of organic disease of the brain.

On the Quantitative Estimation of the Bactericidal Power of the Blood.—By A. E. Wright. Second paper (first paper in *Lancet* of December 1, 1900). A full account with statistical tables is given of the author's experiments, which show in his estimation the following facts: What is measured by the gelatin method described in his former communication is rather the total antibacterial power of the blood than the bactericidal power proper. To determine how much of the result which is registered is referable to an inhibition of the growth of the bacteria, and how much to a direct bactericidal action, it is necessary, after the cultivation-tubes have been incubated and examined microscopically, to melt down the gelatin and to blow out the contents of the tubes into sterile nutrient broth. When it is desired separately to estimate the bactericidal power, this can readily be done by making a series of graduated dilutions of a bacterial cultivation in broth, and by mixing one volume of each of these with one volume of undiluted—or, if necessity should arise, diluted—serum. This method may appropriately be applied when we are dealing with bacteria, such as the vibrio of cholera or the typhoid and diphtheria bacilli, which are readily killed off by the normal human blood. When the method last in question is employed, and when the bacteria in the culture employed have been enumerated in the manner indicated, a convenient arithmetical expression for the bactericidal power is obtained by specifying the number of micro-organisms which one cubic millimetre of serum is capable of killing. When (as in the case of the staphylococcus and apparently, also, in the case of the streptococcus and bacillus of plague) we have to deal with bacteria which are not killed off, or which are killed off only in small numbers, by the normal human blood, or, again, when we are dealing with conditions such as those frequently met with in persons recently convalescent from typhoid fever, when the blood has lost much of its normal bactericidal power, the gelatin method, measuring as it does the combined inhibitory and bactericidal power, may appropriately find application.

On the Influence of Ozone on the Vitality of Some Pathogenic and Other Bacteria.—By A. Ransome and A. G. R. Foulerton. The authors conclude from their own experiments that ozone, in the dry state and moderately strong, has no appreciable effect on the vitality of most of the common bacteria, such, for instance, as the following: Sarcina ventriculi; micrococcus melitensis; micrococcus

candicans; bacillus mallei; bacillus diphtheriæ; bacillus anthracis (from twenty-four-hour-old culture in broth, non-sporing); bacillus anthracis (from old sporing culture on potato); bacillus typhosus; bacillus coli communis; bacillus pyocyaneus; bacillus pneumoniæ; and bacillus prodigiosus. Nor did a prolonged exposure to ozone diminish in any way the pathogenic virulence of bacillus tuberculosis in sputum. Single experiments would also tend to show that ozone can have little if any effect on the pathogenic virulence of bacillus mallei and bacillus anthracis. On the other hand, ozone probably possesses a bactericidal property when passed through a fluid medium containing bacteria in suspension. A comparison of the inactivity of ozone as a disinfectant in the dry state, with its action in the presence of water, suggests a superficial resemblance with other gases, such as chlorine and sulphur dioxide. In the dry state, and under the conditions in which it occurs in nature, ozone, then, is not capable of any injurious action on bacteria, so far as can be judged from the experiments here detailed; and the authors conclude that any purifying action which ozone may have in the economy of nature is due to the direct chemical oxidation of putrescible organic matter, and that it does not in any way hinder the action of bacteria, which latter are, indeed, in their own way working toward the same end as is the ozone itself, in resolving dead organic matter to simpler non-putrescible substances.

A Method of Distinguishing Bacillus Coli Communis from Bacillus Typhosus by the Use of Neutral Red.—W. Hunter maintains: (1) That bacillus coli communis possesses to a marked degree the power of reducing neutral red, producing a superb canary yellow fluorescent color of the medium. (2) That the so-called bacillus enteritidis of Gaertner also produces this reaction, and is probably only a variety of bacillus coli communis. (3) That the bacillus typhosus never possesses this power of reduction. (4) That the common pathogenic micro-organisms do not give this reaction. (5) That by means of neutral red it is possible within from twelve to twenty-four hours to diagnose with absolute accuracy the presence of bacillus coli communis. Finally, as far as his experience goes, it is possible to diagnose by means of neutral red the true coli group from the typhoid group of micro-organisms.

Notes on a Case of Influenza with Meningitis as a Complication.—By A. Foster. The patient was a woman aged fifty-five years, who fell ill with general grippe symptoms, and on the third day developed meningeal complications. She died from the latter complications two days later. The author considers death from influenza meningitis to be of rare occurrence. Two forms are described: (1) That in which there is a simple benign lesion, seldom fatal and which is due to the special action of the toxins secreted by the influenza microbes, producing inhibition phenomena, toxins which appear to have a predilection for the nerve centres and for which the cerebro-spinal fluid serves as a receptacle. (2) That in which the lesion is more severe, generally fatal, and in which the streptococcus, staphylococcus, or other bacilli play an important part.

Three Cases of Cervical Spina Bifida Treated as Out-Patients by Open Operation.—By J. H. Nicoll. All three ended in recovery, two of them being pure meningoceles and the operations presenting nothing of special interest. Cervical cases are the best for post-operative treatment as out-patients.

Four Cases in which Pain was Relieved by Suprarenal Extract.—By E. A. Peters. The designations of the cases are, respectively, recurrent scirrhus of the mamma, stricture of the œsophagus (cancer?), tuberculosis of the larynx and periodontitis.

Result of Major Amputations Treated Antiseptically in the Royal Infirmary, Newcastle-on-Tyne, during the Year 1899 and for Twenty-One Years and Nine Months, viz., from April 1, 1878, to December 31, 1899.—By H. Brunton Angus.

A Case of Fracture of the Sternum.—By J. S. Martin.

A Case of Cerebro-Spinal Meningitis.—By F. Riley.

History of Renal Surgery.—By David Newman.

Ad Terram.—By Sir F. S. Haden.

British Medical Journal, March 2, 1901.

Ad Terram; the Earth and the Soil.—Sir Francis Seymour Haden considers that soil is manure, the very medium in which with so much confidence we are making our experiments—the one great fertilizing agent, without which the earth would starve, its populations die out, and the atmosphere itself, deprived as it would then be of its means of renewal, and being, consequently, without a purpose, might, not impossibly, also cease to exist. The writer believes the earth to be the very opposite of all this. The soil is organic, the earth, inorganic. While the soil has its origin on the periphery of the globe, the earth has its origin in its own centre, and its earliest development is the breaking up and gradual disintegration of its own primitive rocks, till at last they are reduced to the friable matter which we know as "earth." As to the age of these two bodies, while that of the soil can in no case exceed the age of the animal or vegetable which produces it, the age of the earth is measurable only by the countless ages during which we know it to have been in the course of formation. These bodies can have nothing in common till by a provision of nature (gravitation?) they are brought into actual contact, giving rise on their admixture to a change of their elements, or to the creation of a new force. For the interposition of the microbe in changes and metamorphoses of this kind, the writer sees no necessity, or for the interposition of any foreign body. The physical properties of the soil, its weight, its volume, and its great value as a fertilizing agent are measurable only by the whole extent of the earth's surface, and by the amount of organic life, animal as well as vegetable, which is its immediate source of supply. As to its weight and the pressure which it exerts on the earth's surface, it is that of the atmosphere, plus its own density, and the weight represented by the pressure which it exercises on the earth as the effect of gravitation. The writer calls attention to the difference between his views and those of other investigators as depending on the fact that, while they have made most of their experiments within doors, and on the strength of prearranged lines of inquiry, he has worked wholly out of doors, and on lines suggested simply by what he has met with and seen there.

The Campaign against Ague.—Herbert E. Durham has observed that all the pools in which he has met with anopheles larvæ have been muddy and without manifest green growth. As to the use of culicicidal agents, the most profitable time for their employment would be during the dry season, especially at its close. Nature's own culicicides, in the form of tadpoles, water beetles, etc., may be enabled to spread from pool to pool, and assist in the destruction of the anopheles larvæ. As to quinine, its administration causes a rapid disappearance of the malaria parasite in its asexual form from the blood, but the sexual forms can still be found, even after long periods of quinine taking. The writer believes that arsenic is the best drug now known for destroying the sexual forms. For the patient's own safety he must be given quinine in some form or other; for the safety of the community he must at the same time be given some drug such as arsenic.

A Case of Puerperal Eclampsia and its Treatment by Morphine.—George Elder reports a case of this kind in which one-third grain of morphine hypodermically administered stopped the convulsions and produced two hours' sleep. He states that, after making due allowance for cases having other than a renal origin, it must be admitted that the majority have that origin. Prophylaxis is what is wanted in the treatment of this affection. As soon as there is evidence of kidney failure, a rigid milk diet, measures for stimulating the functions of the skin, the kidneys, and the bowels, would generally obviate the necessity of premature induction of labor.

Concerning the Histological Process in Acute Epididymitis.—Ch. Andry and Dalons give the following *résumé* of their paper: As to the initial localization of the lesions, it can be accepted that in the suppurative cases of epididymitis of blennorrhagia this must be searched for in the intertubular connective tissue and in the region of the lymphatics. The same conclusion is applicable, but less strictly so, in subacute epididymitis. The lesions of the epithelium show similar characteristics, principally an energetic metaplasia tending to revert to the cubical type, low and bare—the cylindrical and ciliated epithelium of the cones as well as that of the canal of the epididymis. This change may come from the action of the contents of the tubes, or it may

be from troubles of nutrition. In subacute epididymitis it is observed that the epithelium is influenced at first by these same causes, and besides by the energetic action of the intra-epithelial diapedesis. In a general way the lesions of the cones and of the canal are similar; in a general manner there exist constantly healthy areas in this infected region. The contents of the cones and of the canal are composed sometimes of leucocytes, and sometimes of leucocytes and spermatozoa. In acute epididymitis the leucocytes have not traversed the walls which contain them, at least at those points which were examined. It is not the same in subacute epididymitis. Epididymectomy, total and systematic, is the proceeding most rapid and most sure in the treatment of suppurative non-tuberculous epididymitis.—*Archives Provinciales de Chirurgie*, February 1, 1901.

The Diazo Reaction of Ehrlich in Variola.—Ed. Sergent states that this reaction was seen the first time by Ehrlich in 1882, in the urine of typhoid-fever patients, and has never been found in the urine of healthy persons. The illnesses in which it appears in the urine are very different. They can be ranged in three groups, according to Zunz: Those in which this reaction appears from the beginning, as in typhoid fever; those in which it appears only at the end of the disease, as in pulmonary tuberculosis; and those in which it is rare. Its presence constitutes an element of diagnosis for typhoid fever, and an element of prognosis for pulmonary tuberculosis. The urine of 53 patients ill with variola was examined daily in the Pasteur Hospital. During the eruption the reaction was positive in 9 cases, negative in 2 cases. During suppuration it was positive in 31 cases, negative in 4 cases. During desiccation it was positive in 9 cases, negative in 42 cases. Since the diazo reaction is almost constantly present in the course of variola in full evolution, it would seem to offer a factor of differential diagnosis between variola and varicella, which latter, according to those who have studied the disease, does not as a rule show the diazo reaction. Although the observations so far made are not numerous enough for a conclusion to be drawn, nevertheless they are suggestive. —*Le Bulletin Médical*, February 16, 1901.

Gelatinized Serum in Gynæcology.—Lafond-Grellety believes that gelatinized serum is the most convenient and the surest hæmostatic in the hemorrhages of pregnancy; that in endometritis and in metritis it always arrests hemorrhage, it diminishes leucorrhœa without curing it, and it renders the uterine mucosa less liable to hemorrhage during curettage. He also believes that in curettage, with or without amputation of the cervix, it permits of hæmostasis, without hindrance during the operation. It economizes for the patient a certain amount of chloroform. It renders possible, together with the aid of appropriate solutions, antisepsis of the field of operation. It has the advantage over hæmostatic forceps in that it does not constrict a region that is not easily accessible and which is limited. He believes also that in inoperable cancers of the uterus it arrests and diminishes the frequency of hemorrhage, and it relieves, for some time at least, the suffering attendant upon this affliction.—*Gazette hebdomadaire des Sciences Médicales de Bordeaux*, February 19, 1901.

Contribution to the Study of the Perforation of the Skull by Sarcomata which Originate in the Orbit.—Vieusse presents the following conclusions: Sarcomata which develop in the orbit are almost all melanotic in type; they are essentially malignant tumors, often causing the death of the patient. Their malignancy appears to be due to the pigmented material which they contain. In certain cases, not numerous it is true, the neoplasm penetrates into the skull by breaking through the walls of the orbit; it does not ordinarily cause cerebral troubles, because that part of the tumor which invades the cranial cavity is smaller and develops slowly. The perforation of the skull by a sarcoma of the orbit has no influence on the surgical treatment which these tumors demand.—*Recueil D'Ophthalmologie*, December, 1900.

A Foreign Body in the Rectum.—A. Fraikin reports this case. The patient was a man aged fifty-four years, who came to the surgeon in order to have a foreign body extracted from the rectum. This was done by means of the hand. It proved to be a paint-brush handle sixteen centimetres long and as large as two fists. It had caused no functional trouble. It was extracted without pain and without entailing any complication.—*Journal de Médecine de Bordeaux*, February 10, 1901.

Münchener med. Wochenschrift, Feb. 5 and 12, 1901.

Acute Puerperal Inversion of the Uterus.—A. Fleischmann calls attention to the extreme rarity of this accident, for in a period of fifty-four years, during which 200,000 patients were delivered, it was not observed at the St. Petersburg Lying-in Hospital, and at the London Maternity Hospital 140,800 deliveries were made without its occurrence. Great interest, therefore, attaches to two cases which he reports. The first was that of a primipara in whom the uterus did not contract after the child was born, and which was refractory to the usual methods of stimulation. As some bleeding was going on, an attempt was made to expel the placenta by Credé's method, with the result that the organ suddenly slipped from the compressing hand and a moment later appeared at the vulvar outlet. The patient at once went into collapse, which persisted while the placenta was peeled from the inverted uterine surface and during the act of reposition, which was successfully accomplished by gently compressing the tumor till it could be replaced in the vagina, when by dilating the tightly contracted cervix with the outspread fingers of one hand under simultaneous pressure on the fundus with the palm, it was possible to effect its return to its normal position. Under ergot and hot lysol injections it speedily contracted and the patient made an uncomplicated recovery. In the other case the accident was caused by an effort on the part of a midwife to extract the placenta by traction on the cord. When the patient came under observation, she was unconscious and pulseless. Reposition was readily effected, and prompt recovery from shock followed appropriate stimulation. The most striking observation in both of these cases is the severe general prostration produced instantly on the occurrence of the inversion, which receded just as promptly when reposition had been accomplished.

Intermittent Fever as a Symptom of Mediastinal Tumor.—K. Witthauer reports a highly interesting case of sarcoma of the mediastinum which progressed under rather unusual circumstances. The patient was a woman aged twenty-four years, who came under treatment for pleurisy with exudation, an unfortunate circumstance, since the slight physical signs which were subsequently elicited, and which were due to the new growth, were very naturally attributed to changes secondary to the pleural inflammation. After the acute stage of the pleurisy had subsided the patient did very well, except that up to the time of her death, a period of five months, every third or fourth day her temperature would go up several degrees and then gradually fall again to normal on the second day. In the fever-free intervals she was up and about, but at each temperature rise she suffered from great prostration, dyspnœa, pain in the cardiac region, and cough. All attempts to discover the cause of this unusual phenomenon were fruitless, and no impression was made by a very extensive antipyretic therapy, while the patient grew gradually weaker and finally succumbed to an attack of acute dyspnœa. On autopsy it was found that the heart was pushed forward by a sarcomatous growth which had actually invaded the auricles themselves and involved the whole lower lobe of the right lung and also pressed on the left bronchus. Apparently, the only conclusion possible is that the tumor in some way, perhaps by a more or less regular liberation of toxins, caused the fever, and that this must therefore be included in the list of symptoms of the disease.

The Treatment of Eczema.—Kromayer and Grüneberg sum up the indications for the treatment of eczema as follows: (1) The skin must be set at rest and protected against external and internal injuries, by the application of bland powders, ointments, or moist dressings. This alone is sufficient to insure the cure of all acute cases. (2) Dispersion of chronic tissue changes in old-standing cases by means of reducing agents such as tar, sulphur, pyrogallol, chrysarobin, etc. Since most eczemas are combinations of acute and chronic inflammations, these two indications are often opposed to each other. (3) In obstinate cases cauterization by means of caustic potash or green soap, or preferably by the application of lenigallol. This is the triacetate of pyrogallic acid, and has the property of liberating pyrogallic acid when it is brought into contact with inflamed skin. Its advantages are that it is unirritating, since on normal skin it remains unchanged; that on chronically inflamed surfaces the liberation of pyrogallol takes place very slowly, and therefore it is milder in its action than pyrogallic acid itself; while in spots where the horny layer has been lost its decomposition takes place much more rapidly and its effect is more powerful. When the lesion is deep seated, lenigallol alone is not sufficient to effect a cure, but its application must be followed by some stronger preparation such as tar, while milder forms may be quickly relieved by the use of lenigallol alone.

Quinic Acid, a New Remedy for Gout.—Hugo Sternfeld reports very favorably on this agent as a uric-acid solvent. Quinic acid, which in contradistinction to quinine does not exhibit any untoward by-effects, is in the body converted into benzoic acid, and this again into hippuric acid, which, while closely related to uric acid, greatly surpasses it in solubility in water. By combining it with some diuretic an increased excretion of uric acid follows and the

preparation that has been found most suitable is a quinate of lithium. This is best given in tablets containing gr. viiss., of which ten a day may be administered. The only objection that can be urged against the preparation is its expense, while the results are so gratifying as to justify the conclusion that this agent is as specific for gout as the salicylates are for rheumatism or quinine is for malaria.

Perineuritis of the Sacral Plexus and its Treatment.—A. Guttenberg describes a form of inflammation of the pelvic nerve trunks which is most common in women and is characterized by beaded thickenings along the course of the nerves. The symptoms vary according to the number of nerves implicated and to whether the disease is on one or both sides. At first there is a vague sense of pelvic discomfort, with pain in the loins and back and coxalgia; later on pain develops in the sexual organs and bladder, and extends down the thigh to the knee or even the foot. Walking and stooping are painful, as is extension of the leg, while secondary atrophy of the muscles, due to inactivity, may be observed. The treatment consists of general tonic therapy, together with local massage and passive movements of the limbs.

What is the Value of Tetanus Antitoxin in Human Tetanus?—Wilms would set the value of serum therapy for this disease very low, since in four successive cases treated by him in this way the fatal termination was not averted. Behring has postulated that any case, in order to have value as evidence for or against the serum, must have received antitoxin injections not later than thirty hours after the first tetanus symptoms have been noted, and that not less than one hundred antitoxin units must have been employed. In Wilms' cases these conditions were more than fulfilled, yet death occurred on the second, third, fourth, and sixth days of the disease respectively, and the course of the malady did not seem to be in any way affected by the injections.

A New Medico-Legal Test for Distinguishing between Human and Animal Blood.—By A. Wassermann and A. Schnetze. This procedure is based upon the experiments of Bordet with hæmolysin and precipitin. Bordet showed that, after the incorporation of the red blood cells of a species of animal different from that experimented on, there were developed, in the blood of the latter, substances which combine the red cells (agglutinin) and other substances which decompose them (hæmolysin). The test is made in the following manner: Rabbits are injected five or six times with eight to ten cubic centimetres of human blood serum. Six days after the last injection, the animals are bled by opening the carotid and the blood is allowed to separate, under a very low temperature, into clot and serum. A portion of the suspicious substance to be tested is washed with physiological salt solution, which is filtered until completely clear, and the clear filtrate is divided into two portions which are placed in sterilized vessels. To one vessel is added one-half cubic centimetre of the serum of a rabbit treated with human serum, and to the other a similar quantity of the blood of a rabbit not so treated. In a third vessel, serving also as a control, are placed four or five cubic centimetres of a blood from some other animal, such as a sheep or swine, the solution being made colorless by the removal of the red cells, and to this third vessel is also added one-half centimetre of blood of a rabbit treated with human serum. The three vessels are then placed in a temperature of 37° C. In the course of an hour the vessel which contains the suspicious material, and to which has been added the blood of the rabbit treated with human serum, begins to show a turbidity and a precipitate, while the contents of both the other vessels remain clear and unchanged. The resulting turbidity and precipitate are to be taken as evidence that the suspicious material examined contains human blood, for no other blood except that of the ass will give such a reaction. The authors claim that this test is applicable in the case of suspicious material, when it is impossible to obtain for recognition intact red cells, and even when it is no longer possible to extract hæmin crystals.

Abortion from Poisoning.—G. Schwarzwaeller gives the clinical histories of several cases of abortion, in which various preparations of lead had been taken with criminal intent. He advises that a careful examination of the gums be made in all cases of abortion from obscure causes.

American Journal of the Medical Sciences, March, 1901.

A Study of Congenital Sarcoma of the Liver and Suprarenal.—William Pepper reports a case of this kind which came under his observation. From a search through the literature he finds five similar cases, and tabulates the points of resemblance as follows: The early age of which the first symptom—swelling of the abdomen—was observed, varying from the time of birth to five weeks. This seems to prove the congenital nature of the affection, especially when taking into consideration the extensive involvement of the liver. The time at which the children died varied from ten days to sixteen weeks. This shows great malignancy. The growth of the tumor was rapid. All were females with the exception of one case, of which the sex is not mentioned. The clinical symptoms are: Distention of the abdomen, which was present in all. Wasting existed in varying degrees. Ascites is not noted in any case, nor is jaundice or any form of skin pigmentation. The children all nursed well till shortly before death. There was apparently not much pain, nor is rise of temperature mentioned. There was neither any history nor were signs of syphilis found. The growth of the liver in these cases was identical in its appearance, and showed the same equally infiltrative proliferation by the sarcomatous tissue, with practically complete destruction of the entire normal liver structure. The growth in the suprarenals was very hemorrhagic. In no case was any other organ or part of the body involved by the new growth. The various diagnoses were: round-celled sarcoma, myxosarcoma, and lymphosarcoma. The primary seat in three cases was thought to be the liver; in two, the right suprarenal; in one it was called a sarcoma of the liver and both suprarenals. The absence of the following points in these cases differentiates them from a possible syphilitic affection of the liver and suprarenals: (1) There was no overgrowth of connective tissue in any of the tumor masses. (2) There was no amyloid change in any organ. (3) There was no perihepatitis. (4) There was no jaundice. (5) There was no enlargement of the spleen. (6) There was very little if any pain in the neighborhood of the liver. (7) There was no nephritis. There was a markedly hemorrhagic condition of the tumors. These cases are very dissimilar to all other reported cases of primary sarcoma, either of the suprarenals or of the liver.

The Surgical Treatment of Ascites due to Cirrhosis of the Liver, with Report of Two Cases.—Frederick A. Packard and Robert G. Le Conte conclude that: *A priori* cases of cirrhosis of the liver stand injury badly, and therefore are poor subjects for operation. The resistance of their tissues is presumably much less than in health. The exact estimation of the amount of degeneration of the various organs, including the liver, is extremely difficult or impossible, consequently the mortality of the operation under consideration would naturally be expected to be relatively high. Without operation these patients as a class are doomed to a life of perpetual invalidism, requiring constant treatment and repeated tappings to make life bearable. The writers believe that when the diagnosis of pure portal cirrhosis of the liver can be made, and when persistent and well-directed medical treatment is productive of insignificant results, the operation should be strongly recommended. On the other hand, it would seem that the operation is scarcely indicated, if indeed not contraindicated, in cases of ascites associated with other kinds of cirrhosis (Hanot's, syphilitic, mixed, etc.), or with chronic peritonitis.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENT, HOSPITALS COMMISSION, MINISTERIAL PROMISE, THE HUNTERIAN ORATION—ADJOURNED DEBATE ON ARSENICAL POISONING—MR. V. HORSLEY ON THE MEDICAL COUNCIL.

London, February 22, 1901.

The hospitals commission has already come before parliament, and a measure of reform is promised by Mr. Broderick. Sir Walter Foster once more aired his grievance that the government did not send him on a trip to the Cape as the sanitary adviser. But if the government had wanted an expert on that subject, surely he does not rank as such. Mr. Burdett-Coutts called the conclusions of the commissioners "lame and impotent," and indulged in further abuse in which the member for Bow rivalled him. Mr. Broderick showed that the difficulties of the army medical department had been brought about by the crusade against its cost, undertaken fourteen years ago, and the determination of the House of Commons to reduce the number of doctors and all the expenses of the department. Could they wonder, he said, that when we sent six army corps to South Africa the staff, restricted to three at home and two abroad, was somewhat strained? He acknowledged the great devotion displayed by the doctors under the circumstances, and mentioned some of the grievances that ought to be redressed. He entered on the question of titles, hinted at study leave, and so on. But the great point is that he proved that for fourteen years parliament had kept the department down, and promised if the house supported him that no effort shall be wanting and no prejudice shall be allowed to prevent his giving the army in the future an effective medical service, though he could not pretend to make a complete reform in a few weeks. So far it is well. The responsible minister has promised. The country will support him. The army surgeons may take courage and hope.

The Hunterian oration at the Royal College of Surgeons was delivered, as usual, on the 14th inst. This year the duty was performed by Mr. N. C. Macnamara, who, having referred to the death of the Queen and the interest taken by her late Majesty, as well as by her successor, in all beneficent work, alluded to the loss sustained by the college since the last oration in the death of Sir James Paget. He then passed to the subject he had chosen—craniology. Pointing to the portrait which adorns the walls of the lecture theatre, he remarked that the painter had clearly drawn a human skull and the skull of a chimpanzee on the open pages of the book before Hunter, who he thought was thus shown to be interested in the subject when the portrait was painted. From this the orator proceeded to trace the facts and the speculations which have accumulated as to the relation of man and apes, from Lawrence's lectures at the college in 1819 to Keith's in 1899. The effect of the late closure of the anterior sutures in man on the development of his brain was mentioned, and incidentally that men have, bulk for bulk, four times as much superficial brain surface as anthropoid apes. He agreed with Edinger that the gyri of both brains are similar in character, with the marked exception of the frontal lobes. On which those who do not agree with him might say there is great virtue in the word similar, and the "marked exception" is very marked indeed. Further admitting that in apes the speech centre exists only in a rudimentary condition if at all, the orator thought it probable that to this is due their inferior intelligence, man's intellectual development depending on the possession of the faculty of speech. He attributed the condition of the ape's frontal lobes, to a large extent, to the premature ossification of that part of the skull which encloses the fore-brain, and said the specimens in the museum showed that in the later tertiary and early quaternary period the inhabitants of western Europe resembled, as regards this ossification, the chimpanzee more than the present European. This brought him to the consideration of the skull of man, from the earliest ages to the present time, and the changes in form which have taken places. These changes, largely due to the environment, have occupied long periods of time, and find expression in the hereditary transmission of physical differences among the inhabitants of different regions. To the same causes the orator attributed the development of specialized areas of nerve structure in their brains, by means of which men of the same race come to think and feel alike, and so take common action on matters affecting their well-being, their innate sentiments harmonizing, though they live at great distances and under different climates and environments, because their progenitors developed and transmitted the specialized nerve centres which have become crystallized in their laws, religion, and social institutions.

In illustration of this view, Mr. Macnamara referred to the recent election when he said the inhabitants of England and Scotland, mainly of Anglo-Saxon origin, voted together, while a contrary opinion was held by a greater proportion of the inhabitants of Ireland, and, to a large extent, by the Welsh, most of whom descend from Ibero-Mongolians. He found it difficult to account for this unless we consider it due to racial mental qualities. Environment, he admitted, had played a large part in the evolution of these peoples; but he held that inherited racial character has had more to do with the position which the Anglo-Saxon race has gained than the mineral wealth, climate, or protection afforded by our sea-girt coast.

According to this notion, we owe all our progress in civilization, our intellectual capacity, our laws and social institutions, even our religion, to the exercise over long periods of time of a speck of specialized cerebral tissue, inherited as a speech centre—just as constant practice may develop the fingers of a Paganini—for this is what such evolution amounts to. Nay, "the man that hath no music in his soul" might, by continual practice, develop finer finger muscles than the master, but he could not therefore rival Paganini in making the violin speak. And what about the speech centre of inferior races? Some of them have developed languages the richness and power of which very few have investigated.

The adjourned debate on arsenical beer poisoning, which had been delayed by the special meeting, came off on the 12th inst. It was opened by Dr. E. S. Reynolds, of Manchester, who first traced the cause of the epidemic. He illustrated, by projections of photographs of patients, the succession of the leading symptoms, which usually appeared in the following order: Congestion of the conjunctiva, then of the face and legs, with œdema; erythromelalgia, eruptions, pigmentations, keratosis, etc. The first onset of paralysis is seen in inability to oppose thumb and little finger. He also exhibited for Dr. Delépine photographs of crystals obtained by Reinsch's test of 1 in 100,000 in beer and other things.

Dr. Dixon Mann, of Manchester, referred to the following unusual types: (1) Cases with neither neuritis nor skin lesions, but with sweatings, mental apathy tending towards rambling, weak heart, œdema of the lungs, no pain, fever of 1° to 3°, and sudden death from syncope. (2) Cases without fever, but with tendency to collapse, diarrhœa, vomiting, and other symptoms of subacute arsenical poisoning. The metal, he said, could be detected in the urine one-half hour after taking five minims of liq. arsenicalis, though in fatal acute poisoning it is seldom found in the body if the victim has survived from fourteen to sixteen days. In this epidemic the poison has been cumulative, but time is not the only factor, for none was found post mortem in one woman who died twenty-one days after admission, and in another woman, who survived fifty-two days, it was found. He had seen patients who eliminated arsenic but had no symptom of its presence.

Dr. Judson Berry, of Manchester, had never before seen such severe hyperæsthesia of the limbs, which persisted months after the keratosis and paralysis. In some cases pain and effusion into joints and tenderness of bones were noticed, and he thought the paralysis more widespread than in other forms of peripheral neuritis. In the hand the marked paralysis of extension led to curved fingers. He believed he had seen peripheral neuritis in spirit drinkers.

Dr. Nathan Raw, of Liverpool, found arsenic in five cases out of thirty-three he tested, but never later than ten days after admission. He referred to Osler's observation that liquor arsenicalis had more effect when given in brandy than in water.

Dr. Kelynack showed many photographs, drawings, and casts. He believed the alcoholic vehicle accentuated the effect of the poison. He had seen cases in infants point to elimination through the milk. He thought As_2O_3 in glucose was associated with an acid reaction.

Sir Lauder Brunton mentioned Hunter's experiment showing arsenic to be just as poisonous when absorbed from a wound as when entering by the stomach.

Dr. Luff said he had for a long time been suspicious of arsenic in peripheral neuritis, and had suggested testing the urine in doubtful cases. He had once prescribed five minims, three times a day, of liquor arsenicalis to an adult—an alcoholic. Very soon neuritis set in.

Dr. Tunnicliffe had found selenium in beer, glucose, and sulphuric acid.

Dr. Taylor had observed similar tenderness of the calves of the legs in typhoid, diphtheria, and other conditions.

Dr. Ringer thought the action of arsenic akin to that of potassium salts on the muscles of the skeleton and of the heart.

Mr. Victor Horsley's seventh report to his constituents is an interesting and forcible statement of his work in the General Medical Council and a criticism on the proceedings of that body. He treats particularly of the revolt of the

English colleges, medical aid associations, and finance. On all these subjects I have kept you informed, so I have nothing to add except that, in regard to the last point, Mr. Horsley is very outspoken as to the way in which the chairman of the business committee (Dr. MacAlister) has succeeded for three sessions in shelving this important and unpleasant subject from day to day until the last day, when everything is rushed through in a most unbusinesslike manner. That the council's finance is in a muddle is obvious from the fact that two reports, presented and accepted, positively contradict each other. The council has for years been extravagant and wasteful, and it is time it was sharply pulled up. Another point on which Dr. MacAlister has been obstructive is the personation of practitioners. Mr. Horsley's committee on this subject reported two years ago, but the report is still shelved.

This subject reminds me that a case of personation of a student at a preliminary examination has been detected and taken into court. The judge commented on the laxity of the regulations of the examining bodies concerned in a manner calculated to waken them to a sense of their responsibilities.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 7, 1901.

CHARLES L. DANA, M.D., VICE-PRESIDENT, IN THE CHAIR.

Alcohol as a Food.—This was the topic which Prof. R. H. Chittenden, of Yale, had intended to present, but he was unavoidably absent.

DR. CHARLES L. DANA introduced the subject of the evening with a few remarks. He said that unfortunately the effects of alcohol on the human race had been considered in the past chiefly by sentimentalists, and little had been heard from the medical profession regarding the scientific aspect of this subject. He had himself carefully studied three hundred and fifty cases of alcoholism observed by him at Bellevue Hospital. The most frequent form was periodical dipsomania, and the next pseudo-dispsomania. Over two-thirds of the whole number had begun drinking before the age of twenty, and all before thirty. As a rule, the drunkard did not live more than fifteen years, and it was seldom that the human organism could outlive more than three thousand intoxications. Death usually occurred from pneumonia, meningitis, delirium tremens, insanity, or alcoholic dementia.

Beer Drinking and Kidney Disease.—DR. HERMAN M. BIGGS said that in his early experience at Bellevue Hospital he had seen a large number of cases of cirrhosis of the liver, and the common history had been that of indulgence in large quantities of spirituous liquors—ten to twenty glasses of whiskey a day. But this had all changed in the last fifteen years, and it was the exception to obtain such a history at the present time. The vast majority of the patients now gave a history of taking from one to three drinks of whiskey a day, and four or five pints of beer in the same time. With this change in the mode of drinking there had been a change in the character of the lesions observed. Cirrhosis of the liver was relatively much less frequent, while the degenerative effects, such as disease of the heart, the myocardium, the blood-vessels, and the kidneys, were much more common. Some years ago he had looked up the records of deaths at the health department, and had found that during the last twenty years there had been only a very small increase in the number of deaths recorded as due to alcoholism, hepatitis, and cirrhosis of the liver, in spite of the very large increase in the population. During this period there had been an increase of nearly one hundred and fifty per cent. in deaths from disease of the heart and blood-vessels, while the population had increased only from fifty to sixty per cent. Almost the same was true of diseases of the kidney. In the last twenty-five years lager beer had largely replaced the weiss beer formerly used in Germany, and during this period the death rate from disease of the kidneys had greatly increased. These facts appeared to find their explanation in the change in the type of drinking, *i.e.*, this combination of spirituous and malt liquors.

Effect of Alcohol on the Nerve Centres.—DR. M. ALLEN STARR said that in the majority of individuals sherry produced a quarrelsome mood, while, on the other hand, port tended to exert a soothing effect. Champagne produced apparently a decided exhilaration of the flow of thought, while Burgundy made one think more slowly and by no means added to the feeling of conviviality. Whiskey, brandy, and gin had very different effects on the individual; hence, we should remember that we were not dealing with the effects of alcohol *per se*, but with its effects in certain combinations. There was no known disease of the spinal cord produced by alcoholism, although we knew of distinct effects upon the nerves and upon the brain as a result of alcoholism. The alcohol seemed to affect the parts of the brain which were the most highly organized and developed. The highest centres were the ones first attacked; the intermediate centres, and the lower centres of the brain and the spinal cord, did not seem to be specially susceptible to alcohol. The pathology of alcoholic insanity was to-day most clear and distinct. Berkeley had shown that the alcohol acted upon the brain by dissolving, as it were, the dendrites and so rendering the cells incapable of receiving impulses from other cells; hence, the lack of co-ordination and loss of memory, so evident in all conditions of chronic alcoholic insanity.

Care and Treatment of Inebriates.—The hypodermic use of strychnine and atropine was now generally agreed to be the chief measure of usefulness, together with proper attention to the nutrition in cases of acute alcoholism. He did not think it was very common to find a recovery from chronic alcoholism of the type of periodical drinking in which there was an entire cessation of the drinking between the attacks. This form, he believed, was more a matter of moral obliquity than of true insanity. The diagnosis of insanity could not be made from a single symptom; there must be something more than a mere tendency to drinking on which to base the diagnosis.

Religious Influence Potent.—Dr. Starr thought the physician or the family should be able to control these persons legally. A certain amount of moral suasion seemed to be of much more service than anything in the way of medicinal treatment. Most of these individuals were neurasthenic, and if their neurasthenia could be improved their power to resist the drink impulse could be augmented. He was of the opinion that any measure of a religious or of a social character that could be brought to bear on these individuals was well worthy of trial, and he would confess that the only reformed drunkards of whom he had knowledge were those who had been saved, not through medical but through religious influence. After an extensive experience with various institutions, he did not hesitate to say that he did not know of a single one in which it was not comparatively easy for the inmates to secure alcoholic liquors. If we could legalize the commitment of a chronic alcoholic for a certain period to a place where he could be kept from alcohol, it might be possible to save some of these unfortunates. It was well worth while to make an effort in this direction.

DR. ALEXANDER LAMBERT said that he had not gone into a minute study of the alcoholic patients in Bellevue Hospital, because he had long ago lost all faith in their statements. Certainly there was a great differ-

ence in the symptoms presented by those who had been accustomed to drink good liquor, and those who had indulged in the vile spirits of the east-side saloons. Of the twenty-four thousand and three hundred patients in Bellevue Hospital last year, over one-fourth went through the alcoholic wards. Last summer he had tried the effect of threatening the "repeaters" with the workhouse, and had found that in the ensuing six weeks the number of these repeaters had been reduced from sixty to twelve; while in the women's wards, where no such threat had been made, there had been the normal percentage of repeaters. When it had been discovered that this threat was not to be carried out, the usual number of male repeaters came into the wards. Among these patients there were many who had taken the various "cures." Unless we had some law, as in Connecticut, which would permit the detention of the alcoholic until sufficiently recovered to be allowed to go out, the outlook from treatment must be most discouraging. Regarding the question of heredity, statistics were cited to show the enormously large number of defective and diseased children among the progeny of alcoholic parents.

Effect of Alcohol on the Ganglion Cells.—Dr. James Ewing said that he had been interested in the study of the effects of alcohol on the ganglion cells. The cases were conveniently divided into two main classes, viz.: (1) Those which were acute, and (2) those which were very chronic. In the brains of those dying from delirium tremens the appearance was most characteristic, particularly the great venous engorgement on gross examination. On microscopical study with the aid of Nissl's or Golgi's stain, one found changes which were apparently identical with those observed in sunstroke, tetanus, and hydrophobia. There was a complete disappearance of the reserve nutriment or chromophilic bodies. The distribution of the lesions showed that there was a general circulating poison. He had found the lesions in the motor cortex as well as in the less complex cells of the frontal lobes. As a rule, the spinal-cord cells did not show such marked lesions as did the ganglion cells of the brain cortex. Several systematic attempts had been made to reproduce in the lower animals the same condition as delirium tremens of human beings, but so far these had all been failures because if sufficient alcohol were given it acted as an irritant, causing the death of the animal. These experiments perhaps justified the deduction that alcohol acted chiefly on the more highly organized cells of the nervous system. Such lesions as were produced resembled those of chronic alcoholism in man. The chronic abuse of alcohol was followed by distinct lesions in the human subject, though not so marked as in the acute cases. In the brain of the average chronic alcohólic, one found an evidence of wear and tear in the deposit of pigment, usually in large masses in the ganglion cells. Those who were engaged in making autopsies in the hospitals of New York City, he thought, would bear out the statement that the visceral lesions of alcohol were more prominent than were those of either tuberculosis or syphilis.

The Law and the Inebriate.—Dr. Joseph Collins said that it was generally conceded that the habitual inebriate could be reached only by legislation. Strangely enough, New Zealand and Switzerland had led the world in this important matter. Nearly all of the provinces of the Dominion of Canada had passed effective legislation for the care of the inebriate, but legislation for this class in the United States had been spasmodic, desultory, and wholly unsatisfactory. The author then reviewed the laws bearing on this subject that had been enacted in various countries.

Alcoholism and Tuberculosis.—Dr. S. A. Knopf said that alcoholism was a pronounced factor in tuberculosis. Statistics showed that twenty-five per cent. of children committed to sanatoria for the treatment of scrofulous and tuberculous diseases had alcoholic parents. It should be remembered that there was a very prevalent opinion among the laity, and to a certain extent among physicians, that alcohol was a most important agent in the treatment of consumption. If alcohol were given in quantities sufficient to control the temperature, it would convert the phthisical patient into an alcoholic. As to the treatment of inebriates, the speaker said that he approved of moral suasion, arguments, and hypnotic suggestion. Poor tenements and poor cooking were potent factors in the production of alcoholism.

Ignorance a Cause of Alcoholism.—Dr. G. L. Peabody said that the last speaker had sounded the true note when he had called attention to ignorance of the effects of alcohol as a cause of alcoholism. This ignorance was common among people who were by no means ignorant on other matters. They were disposed to think that there was no particular harm in drinking spirits so long as one did not get actually drunk; they did not know, or else ignored, the pathological effect of continued moderate drinking. In these days of working under high pressure, the fatigue experienced toward the end of the day was a cause of indulgence in alcohol. Many business men thought they must take some alcoholic beverage at night either with or before their dinner. At one time the Massachusetts State board of health had analyzed twenty or thirty specimens of "bitters" found in the market. Many of these were recommended as substitutes for alcohol, and as conducive to temperance, yet they were found to contain from forty to fifty per cent. of alcohol. The fact was commonly overlooked that sherry wine was not really a wine in the dictionary sense of that term, but really a flavored spirit containing from thirty to forty-five per cent. of alcohol. Ladies would often take sherry wine, because it was called a wine, though they would shrink from taking any spirit.

Methods of the Gold Cures.—Dr. Peabody said that he had been told by a physician that in the so-called "gold cures" it was the practice to give daily hypodermic injections of strychnine and atropine, the solution being of a golden color, but not containing any gold. After the treatment had been carried out along this line for a certain length of time, the patient was told that he could, if he so desired, go to the sideboard and help himself to liquor in the presence of the physician. Some would accept this invitation. They would then receive what was apparently the customary hypodermic injection, but it was not really so, the physician having smuggled in a dose of apomorphine. Of course, when shortly afterward the patient vomited the liquor, he would be profoundly impressed and disposed to believe the statement made to him that after having gone through the "cure" it would be impossible for him to "digest and retain" liquor, even if he saw fit to take it.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, February 28, 1901.

J. Riddle Goffe, M.D., Chairman.

A Case of Pelvic Suppuration.—Dr. A. Brothers reported this case, and presented the specimen. The patient, a prostitute thirty years of age, had enjoyed good health up to eight days before coming under observation on February 9, 1901. At that time she had developed an intense pain in the right side of the pelvis. On examination he had found a partially mov-

able round tumor on the right side, surmounted by a cylindrical ridge. The tumor was soft and the size of an ordinary apple. A diagnosis of ovarian abscess with agglutinated pus tube was made. She had remained in bed for three days with an ice bag over the hypogastrium, and had frequently used hot douches. The tumor had increased in size. She would not consent at the time to operation, but was finally operated upon on February 18th, in hospital. At that time the tumor was the size of a small cocoanut. It was found to consist of a large ovarian abscess, with agglutinated pus attached to its upper surface. There were firm adhesions to the omentum and to contiguous structures in the deep pelvis. In the process of enucleation the ovarian abscess had been ruptured, and upward of half a pint of greenish pus had escaped. This was mopped out, and peroxide of hydrogen poured into the pelvic cavity. There was an ovarian abscess on the opposite side, about the size of a plum. This was extricated with much difficulty from the surrounding adhesions, and the wound closed without flushing or drainage, three tiers of sutures having been used. One of the house staff, who examined the pus, reported that he found no gonococci or other microorganisms. With the exception of a mild bronchitis and an occasional evening rise of temperature to 101° F., the patient had made an uneventful recovery. The speaker said that the temptation in this case to incise and drain the abscess per vaginam had been great, and while this would unquestionably have given her temporary relief, it would have left a pus sac and a purulent tube on the right side, and an unrecognized smaller tubo-ovarian abscess on the left side, not to mention the adherent omentum above and the numerous pelvic adhesions of the tumors below. He had felt that he was warranted in omitting both flushing of the cavity and drainage, for the following reasons: (1) Gonorrhœal pus was conceded to be the least virulent form known; (2) the tumors were walled off from the general peritoneal cavity with sterile gauze pads before enucleation was attempted; (3) the table was lowered from the Trendelenburg position the instant the rupture occurred; (4) the free pus was mopped up as quickly as possible, and the tumor removed; (5) peroxide of hydrogen was poured into the wound to neutralize the possible septic effects of the pus; (6) the operator wore rubber gloves, which were discarded after the cleansing of the abdominal wound with corrosive sublimate, and all infected instruments, towels, and pads were put to one side after careful wiping of the pelvic cavity, previous to closure of the abdominal incision.

Dr. Ralph Waldo objected to flushing of the peritoneal cavity because such a procedure disseminated the septic material, and mere flushing was not in itself sufficient to remove such matter. It was a rare thing to find sterile pus after careful bacteriological examination. Such an examination presupposed that the pus had been kept in an incubator for at least three or four days.

Dr. H. N. Vineberg remarked that the report of one case of recovery without drainage by no means proved that this practice should be generally followed. In his experience the question of drainage was not so much whether there was pus present or not, but whether or not there was a large, raw surface present for absorption.

Dr. George Gray Ward referred to a recent case of rupture of the tube during operation, in which he had used full-strength peroxide of hydrogen, and had then washed the cavity with water and drained. In this case primary union had occurred, and the patient had made a good recovery. In another case, in which peroxide of hydrogen had been used, no drainage had been employed, and this patient had also recovered.

Dr. Philander A. Harris said that the evacuation of an ovarian abscess through the vagina did not usually secure a complete cure.

Dr. A. Ernest Gallant pointed out that bacteria lost their virulence in old pus tubes. Excellent results followed closure without drainage, and, in a general way, it might be said that the results were best in those cases in which the least was done.

Dr. Le Roy Broun said that he had supposed that the consensus of opinion was in favor of draining ovarian abscesses through the vagina, and doing a more radical operation later if required. This seemed to be a more conservative practice.

Dr. J. Riddle Goffe said that the tumors presented could have been removed just as well per vaginam as by abdominal section.

Dr. Brothers said that it was now recognized that certain cases did not require the elaborate flushing and drainage considered absolutely necessary some years ago. This was the general practice, although there were still a few exponents of the older mode of practice. At the present day it seemed foolish to resort to incision and drainage, with the tiresome secondary operations and tedious convalescence.

Pedunculated Fibroid of the Labia Majora.—Dr. L. J. Ladinski presented this specimen, taken from a woman over eighty years of age. A search through the literature had failed to show a single case of fibroid of the labia recorded. The tumor had been noticed about three years, and the growth had undergone spontaneous sloughing, apparently as a result of the closing up of the blood vessels supplying it. He had removed the mass under cocaine anæsthesia, and had closed the gap with sutures.

A Tumor of the Buttock.—Dr. Ladinski also presented a woman who had come to him the day previous. There was a tumor springing from the buttock, which she claimed had existed for fifteen years. There were also a number of sebaceous cysts in the scalp, and it was probable that the tumor of the buttock was also of this nature.

Dr. S. Marx thought it was a fatty tumor undergoing suppuration.

Dr. Gallant thought, from the appearance and feel, that it was a sebaceous cyst. He had seen a number of such growths.

Dr. Waldo said that some years ago he had assisted in the removal of a similar tumor, except that it was much larger, in the same locality. The pedicle sprang from the cutaneous surface of the labium majus.

Anencephalic Monster.—Dr. S. Marx presented this specimen, which had been taken from a woman thirty-three years of age. This was her tenth pregnancy. Some of the pregnancies had terminated in living children, but not all. The speaker said that he had met with four such cases, and in three of them the diagnosis by palpation had been most difficult, but in each instance it was worthy of note that as soon as the fœtus had been touched by the examining finger it had had a convulsion in utero.

Dr. Malcom McLean said that, while he would pay no attention to maternal impressions in the sixth or eighth month of pregnancy, he had seen a sufficient number of cases in which maternal impressions in the early weeks of pregnancy had been followed by deformity to make him believe there was something in it. For this reason he was interested in the statement of this patient that she had had an impression which had made her fear that her baby would be deformed in the head when born.

Peculiar Globules in the Urine.—Dr. E. J. Ill, of Newark, said that he had drawn the urine by catheter from a woman's bladder and had examined this viscus with the endoscope, with negative result.

On emptying the bladder after the examination he had been surprised to find in the urine numerous globules, the exact nature of which he had been unable to determine. Under the microscope they had resembled smegma. They remained unchanged on boiling, were not dissolved by ether or saponified by alkali.

Dr. M. McLean said that some years ago he had presented a specimen of urine containing very similar globules in enormous numbers. These bodies had been passed periodically, usually at intervals of a few days, and sometimes in quantities of half an ounce at a time. These bodies had been proved to be a form of fatty matter, encrusted with other products, but no satisfactory explanation of their occurrence had ever been offered.

Present Technique in Operations for Repair of Complete and Incomplete Lacerations.—Dr. H. J. Boldt opened a discussion on this subject. He said that after having tried various methods he had come back to the flap-splitting operation revived by the late Mr. Lawson Tait. It was especially satisfactory, because it avoided loss of tissue in the event of there being a failure to secure primary union. By that method he had had no failures, which was more than he could say of the other methods tried. In a multiparous woman, having retroflexion of the uterus and laceration of the perineum, the primary treatment should be rectification of the uterine displacement. When there were deep lateral scars, these should be excised.

Dr. Le Roy Broun said that he had been unable to get as good anatomical results by the flap-splitting operation as by the more generally adopted Emmet operation. But even the best operators conceded that there would be occasional failures in operations for complete laceration. Dr. Emmet always used one line of sutures, introducing these down to, but not through, the rectal mucous membrane. There was apt to be a sinus extending into the rectum above the sphincter muscle. He would attribute this sinus to the liability by this method of missing the fibrous coat of Halsted. It had been shown that when this coat was not included in the suture the hold of the latter was not secure, and as this fibrous coat was close to the mucous membrane the advantage of including the mucous membrane was obvious. The speaker said that he had practised the method of inserting a fine silkworm-gut interrupted suture through this fibrous coat, and had had uniformly good results. The essential point was to pass the sutures through the rectal mucous membrane. He had seen no interference with healing from the pursuit of this course. The fine silkworm gut either rots out in four or five weeks, or may be removed after that time without difficulty. The sutures should be inserted about one-quarter of an inch apart, being entered into the mucous membrane and the fibrous coat and tied on the rectal side. The bowels might be moved on the second day, and the patient allowed ordinary diet.

Dr. Goffe said that in operating upon an incomplete laceration he denuded the necessary area by beginning at the lateral caruncles. This enabled the operator readily to strike the line of cleavage. His first two sutures carried the rectocele up into the vagina, and the next suture, sweeping round widely into the tissues, caught the separated ends of the transverse perineal muscle. The same general method was pursued for complete lacerations, but before passing the sutures he sewed up the rectal wall with an interrupted suture of very light catgut. The sutures were tied on the rectal side, and were expected to come away when the bowels first moved. They were intended to secure good coaptation only temporarily. The last two sutures inserted in this operation took in the ends of the sphincter muscle. He had used this operation for a number of years, and had found it very satisfactory.

Dr. Waldo said that when the laceration was incomplete the operation was done for the purpose of curing the rectocele. When the laceration was complete, the operation was done for curing incontinence of fæces. For the incomplete form it was essential to run up high on the posterior wall, and to denude sufficiently deeply to expose the fascia and muscle. If the denudation were more superficial, the immediate result would be good, but it would not be permanent.

Dr. Ladinski said that for the secondary operation for complete lacerations he had found the flap-splitting operation all-sufficient, but for immediate repair this operation was not well suited, and in these cases he used the operation recommended by Dr. Broun, taking the precaution to stretch the sphincter before the operation and to insert a tampon cannula afterward. When there was very little rectocele, he preferred the Emmet operation.

Dr. Ward exhibited a photograph of a complete tear, showing well the torn ends of the sphincter, and also a photograph giving the result of the operation in that case. He had sewed the rectal wall with sutures of catgut, passed down to the mucous membrane and tied in the wound.

Dr. E. J. Ill said that he was especially interested in the incomplete lacerations. He knew of no surgeon, except the gynæcologist, who would remove normal tissue in performing a plastic operation. If one employed the Hegar denudation, a large amount of normal tissue would be sacrificed. Personally, he made it a practice to remove only scar tissue, lifting up both sides and sewing them together with deep catgut sutures.

Dr. Boldt said that he could not understand why one should desire to remove the vaginal mucous membrane, as it belonged there normally, and such removal of normal tissue was entirely unnecessary, because by a proper flap-splitting operation a perfectly good result could be obtained. It gave a satisfactory result even in complete lacerations. When there was a separation of the vaginal mucous membrane and descent, then denudation was required.

Dr. Gallant said that it might be interesting to many to know just what silkworm gut was. It was obtained by pulling out into strands the mass of gum found in the silkworm. The longer it could be drawn out, the higher its price, because this indicated greater tenuity.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 13, 1901.

Eugene Hodenpyl, M.D., Chairman pro tem.

Ruptured Aneurism of the Basilar Artery.—Dr. O. H. Schultze presented a specimen showing a fusiform aneurism of the basilar artery. It had been taken from a well-nourished man, twenty-eight years of age, who had suddenly collapsed while engaged at his work as stoker on a tugboat. No further history had been obtained. The examination showed that the immediate cause of death had been asphyxia. The blood was fluid, and there was passive hyperæmia of all the organs. Evidence of syphilis was especially looked for, but not found. A small rupture was found with a subpial clot at the base of the brain, and this was the only blood found coagulated in the body. There was a rupture through the roof of the fourth ventricle into the ventricles, which were filled with blood. The aorta showed a marked hypoplasia, corresponding with the development of a young adult woman. The valves of the heart were normal, and the heart itself weighed twelve ounces. The external genitalia were underdeveloped.

Sacculated Aneurism of the Middle Cerebral Artery.—Dr. Schultze also presented a sacculated aneurism of the right middle cerebral artery, near its origin. The ruptured aneurism was covered by a blood clot under the pia, lacerating by compression the cortex of the inner aspect of the right temporal lobe and the pia mater. A very large clot had formed, covering the entire upper and outer surface of the right cerebral hemisphere. The aorta in this case also was markedly hypoplastic, corresponding in development to that of a young adult woman. The muscles and the valves of the heart were quite normal. The aorta showed a very minute lesion of atheroma on the inner aspect of the first portion. There was no history obtained in connection with this case. The man was apparently about thirty years of age, and his muscular development was good. The blood was fluid, and showed that death had occurred by asphyxia from compression of the brain. The specimens were interesting, as showing the absence of syphilis and arteriosclerosis. These cases, the speaker thought, presented an argument in favor of underdevelopment of the arterial system, congenital if not hereditary in origin, as an etiological factor in the formation of aneurism.

Endothelioma of the Breast.—Dr. E. Hodenpyl, in presenting this specimen, said that it was his rule not to make a diagnosis of endothelioma if there was any good reason for calling a tumor anything else. The specimen presented was a tumor of the breast, and he thought it could hardly be called anything else but an endothelioma, although one similar growth had been reported as "a villous carcinoma." The specimen had been taken from an unmarried woman aged sixty years, who had noticed a lump in the left breast for four years before the operation. This had gradually enlarged until the entire organ had become involved. There had been no emaciation or cachexia, and no involvement of the axillary lymph nodes. The radical Halsted operation had been done. After the removal it had been found that almost the entire breast was involved. The tumor was nodular in character, and in places there were hemorrhages and considerable gelatinous infiltration. On section the tumor resembled in its general appearance a papilloma, but on the outlying portions one could see fairly large alveoli, usually lined with a single layer of cells. Some of these cells were almost cylindrical in character. In the smaller alveoli, on the periphery, the growth had made secondary holes with a cell lining. These holes had been found entirely empty, and he was disposed to consider them newly formed lymph channels. Under the microscope the growth bore no resemblance to ordinary carcinoma, and the diagnosis of endothelioma seemed to be warranted.

A Very Large Cyst of the Kidney Removed by Operation.—Dr. Hodenpyl also presented a large multilocular cyst of the kidney which had been taken from a woman fifty-eight years of age, who for fourteen years had noticed a gradual enlargement of the abdomen, principally on the left side. The urine had been examined several times before the operation, and had been found about normal in quantity and in composition. The woman had done well for thirteen days after the operation. The urine had been examined daily after the operation, and for a few days had contained a very slight trace of albumin and a few red cells which had probably arisen from the effect of the operation and the ether. On the 13th she had been suddenly seized with intense pain over the heart, and within five minutes she was dead. No post-mortem examination had been permitted. The tumor retained the general shape of the kidney, and at one end a small portion of the parenchyma of the kidney could be discerned. When fresh the kidney had weighed seven pounds and a half, and had measured thirty inches in circumference, eleven inches in its longest diameter, and six inches in depth. It was almost impossible to say whether this kidney was an acquired condition or was congenital in origin. He was disposed to look upon it as an acquired condition, arising from obstruction produced by a calculus or other obstruction in the ureter.

Dr. Ewing said that he had had an opportunity of carefully studying the tumor of the breast, and it certainly looked very much like an endothelioma, yet at the same time he had seen in the past year or two several tumors which had approached this in type and yet had probably been adeno-carcinomata. However, in neither of these cases had there been the same diffused growth of cells.

Microscopical and Gross Specimens Illustrating the Origin of "Colloid" Carcinoma of the Peritoneum.—Dr. James Ewing said that during the past few years he had been in considerable doubt regarding the origin of the well-known form of colloid carcinoma of the peritoneum, the text-books not stating definitely where these tumors originated. Some of them grew to an enormous size, covering all of the viscera with a thick gelatinous layer, which showed little tendency to infect the bowel. Dr. Jeffries had presented to this society a specimen consisting of a very large number of pearl-like masses scattered all over the peritoneal surface. At that time the general impression had seemed to be that the tumor was made up of the lining epithelium of the peritoneal surface. He had himself been strengthened in this belief by having searched through the entire length of the intestine in two cases without finding any initial lesion throughout the entire mucosa. A few weeks ago he had seen a specimen presenting a very early stage of colloid carcinoma. It was a tumor of the caput coli, causing partial occlusion of the intestine but not involving the peritoneal surface. On section it had presented the typical structure of such growths. This seemed to him to indicate that the growth had developed from the epithelial cells lining the straight tubular glands of the colon. About the same time a small tumor of the colon had come under observation. Sections under the microscope had shown the same general features, yet at the point of demarcation between the normal and affected epithelium there had been a gradual transformation into alveoli. For these reasons he felt constrained to accept the old term of colloid carcinoma. The first specimen presented was a tumor of the caput coli.

Dr. Ewing, continuing, said that there seemed to be two distinct groups of tumors arising from the colon and rectum, viz.: (1) The form just described, and (2) a form of malignant adenoma, which developed large alveoli with very high cells. In addition to these, there was an infiltrating carcinoma, found usually in the form of an ulcer of the rectum or sigmoid. This tumor was entirely different from the second variety. It had almost no alveoli; if they were present, the lining cells were small and low. He had never seen adenoma of the rectum that did not cause ulceration of the intestine. The speaker then presented a specimen from Dr. Buxton's collection, of a papillary adenoma destruens—a rather rare variety. A specimen of the infiltrating variety was also exhibited. As to the exact point of origin of these tumors of the tubular glands of the colon, which presented such distinct varieties, Dr. Ewing said that from the enormous production of mucus in colloid carcinoma it was probable that its origin was the secreting cells, deep down in the tubular glands. Until he had met with the specimens just presented he had never seen any evidence that there was any connection between colloid carcinoma and adenoma destruens, but here he found that the muscular coat was being infiltrated by

a few of the cells of the infiltrating type—in other words, the specimen presented the two types of adenoma destruens and the infiltrating variety. He therefore concluded that all three of the varieties mentioned were derived from the outer or lining cells, which had little power to secrete mucus.

Dr. Hodenpyl asked if he were to understand that all primary cancers of the peritoneum arose from the mucous membrane of the intestine.

Dr. Ewing replied in the affirmative.

Dr. Hodenpyl said he felt sure that he had met with some tumors of the peritoneum that did not have this origin. Moreover, some of these colloid tumors had been found by chemists not to contain mucin.

Dr. Ewing said he did not see how one could prove that the tumor was derived from the lining epithelium.

Dr. Schultze said that when the dissemination was extensive, and yet, as had been said, the intestinal mucous membrane had been found normal, it was difficult to reconcile this with the statement made regarding the origin of such growths. In three cases he had observed a tumor growing from the crypts of the large intestine, about a hazelnut in size, which had reached the peritoneum, and showed a gelatinous character. There was no tumor, strictly speaking, of the peritoneum, but a tumor underneath the peritoneum.

Congenital Cysts of the Kidney.—Dr. Leon T. Le Wald presented these specimens, taken from an adult about forty years of age. Both kidneys were markedly cystic, in spite of the fact that the person had lived to this age. The kidney tissue was found only in the strands between the cysts. Apparently they were of congenital origin. The nature of the urine excreted by this person was not known.

Two Cases of Large Uterine Fibroids Complicated by Pregnancy.—Dr. Le Wald also presented these specimens. The first was from a woman of thirty-eight years. Owing to the very rapid enlargement of the uterus an examination had been made by Dr. Studdiford, and it had been decided to terminate pregnancy. This had been done at the end of the third month. In the second specimen it seemed impossible that pregnancy could have gone on much farther after the time the laparotomy had been decided upon. The woman was thirty-five years of age, and had been operated upon by Dr. Coe.

Tuberculous Appendicitis.—Dr. Le Wald presented a specimen of tuberculous appendicitis, occurring in a case of pulmonary tuberculosis. Practically the only tuberculous process in the intestine had been in the appendix. The latter had been about the size of the index finger, and contained several tuberculous ulcers. Several tubercles had been found on the surface of the appendix. There was no history pointing to the appendix.

Prostatic Hypertrophy.—Dr. A. E. Thayer presented a number of bladders to show prostatic disease and certain other interesting features. The first one showed ordinary hypertrophy of the middle lobe of the prostate, constituting the so-called "ball valve." In the second specimen hypertrophy of the lateral lobes was quite marked, while there was very little in the middle lobe. In another specimen the consistency of the tumor was such as to suggest sarcoma, but the microscope showed it to be an example of ordinary prostatic hypertrophy. Another specimen had been taken from a negro about sixty years of age. This man had been admitted to a hospital, complaining only of extreme weakness. Physical examination of the lungs had shown apparent consolidation on the right side. The temperature had varied between 100° F. and normal. The urine examination had been negative. In two or three days there had been a sudden rise of temperature, and he had died. At the autopsy the lungs had been found to be free from pathological change, except a small area of latent tubercle in the right apex. In the large intestine were old and deeply pigmented tuberculous ulcerations, and a gangrenous colitis. In the bladder were 40 or 50 c.c. of thick, stringy pus, on the inner surface was a recent slough, and in the trigone were a number of tubercles. The prostate was hypertrophied. There was marked interstitial nephritis, and the pelvis of each kidney contained pus.

The Occurrence of the Bacillus Aerogenes Capsulatus in the Human Body.—Dr. Harlow Brooks read this paper, dwelling particularly upon the habitat of this bacillus. He said that the condition was most frequently observed in dead bodies during the warm seasons, and when the body had been transported a considerable distance. Almost invariably the "floaters" recovered from the river showed this condition. In four hundred and twenty-seven autopsies performed by himself in this city, there had been only six of gas infection in which the infection played the chief or an important rôle in causing death. In 1897 he had begun a systematic search for the bacillus in the intestinal tract, and after an intermission had taken up the subject again recently. The material had been at once transferred to tubes containing ordinary bouillon, and the tubes had then been sealed with melted paraffin. They had next been placed in an incubator at 37° C. After twelve to twenty-four hours those in which gas had formed showed the discs of paraffin forced upward. The contents of the tube had then been injected into the ear vein of a rabbit and the animal killed. After some hours, if there was no subcutaneous emphysema, the experiment was considered negative. If, however, this was present and the bacillus was identified in smears from the liver, the experiment was considered to be positive. It had been stated that this bacillus might grow without the formation of gas, but he doubted this statement, although admitting that the quantity of gas produced was very variable. The presence of visceral and subcutaneous emphysema in the rabbit seemed to be quite characteristic. Flexner had shown the presence of this bacillus in the Philippine Islands, and from a personal observation, made while hunting in Newfoundland last summer, Dr. Brooks said he felt sure that the bacillus was present even in that cold region. He had examined for this bacillus twelve cadavers in the order in which they had been received at the morgue, and had found the bacillus present in the intestinal canal in all but one, the body of a child. He had examined the urethra in ten cases giving no evidence of infection, and in three the gas bacillus had been obtained. Cultures from the nasal cavities showed abundant gas formation—indeed, his observations on these cavities and on the vagina had led him to believe that the gas bacillus was nearly always present in these passages, both in the living and in the dead subject. His investigation seemed to point to the fact that the bacillus was particularly prone to infect blood clots and give rise to dangerous infection. The importance of this observation in connection with injuries about the pelvic structures was obvious.

A New Rapid Method of Staining the Chromatin of the Malarial Parasite.—Dr. L. B. Goldhorn was the author of this paper. He said that the staining of the chromatin of the malarial parasite had hitherto been rather difficult. The following method that he had worked out was a very simple one and gave very satisfactory results: Fix the preparation, which must be fresh, by immersion in pure methyl alcohol for fifteen seconds. Wash in running water and stain for from seven to thirty seconds in a 0.1 per cent. aqueous solution of eosin. Wash as before and stain in the polychrome solution for from thirty to sixty seconds. Wash again and dry by agitation of the smear in the air; no filter paper should be used; heat should be avoided.

Should the dye by exposure to the air become too alkaline, add a few drops of a four to five per cent. solution of acetic acid. If too much acid had been put in, a few drops of a saturated aqueous solution of lithium carbonate might be added. The stain improved on keeping. This method, it was stated, supplied the long-felt want of a rapid stain for the demonstration of the chromatin of the malarial parasite. The stain, when properly handled, showed that red blood corpuscles containing malarial parasites underwent a peculiar granular degeneration. Rapidity was combined with most satisfactory results. Separate eosin staining was not absolutely necessary; the eosin might be added to the methyl alcohol. The various granulations of leucocytes were seen. Lymphocytes stained beautifully, and so did the blood platelets; the latter showed a purplish granular network on a bluish body. Red corpuscles showed basophilic degeneration whenever it was present. Polychromatophilic degeneration was well shown. Bacteria stained deeply, and their spores remained unstained. The method gave beautiful clear pictures with the gonococcus. In pernicious anæmia the macrocytes showed frequently deeply stained granules. Certain megaloblasts would be seen to be very closely granular. In lymphatic leukæmia a perfect slide was obtained, and the nucleoli of lymphocytes were readily demonstrated by staining for only a short time in the dye. When a smear was somewhat thick, it might be found to be stained heavily, as the greater quantity of alkaline serum present increased the staining-power. As the alkalinity of the blood varied, results varied accordingly. This stain, which should be kept in well stoppered bottles, had been placed on the market.

Dr. Ewing said that he had had the pleasure of looking over some of the specimens stained by this method, and had been greatly delighted with the results, as any one must be who had struggled for years with the older methods of staining. Dr. Goldhorn was to be congratulated, as this put the finishing-touch on many years of patient investigation. He had found that almost any amount of eosin added to the polychrome methylene blue gave a good result. Apparently the method was particularly suitable for the demonstration of the granular degeneration. It did this very much better than any other method with which he was familiar.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 9, 1901:

	Cases.	Deaths
Tuberculosis	320	170
Typhoid fever	22	12
Scarlet fever	562	32
Measles	274	8
Diphtheria and croup	261	44
Smallpox	54	10
Varicella	65	0

Quinine Hæmoglobinuria.—Dr. Welsford, of Johannesberg, says: "With regard to the theory that the so-called blackwater fever of the tropics is a peculiar condition caused by the administration of quinine in malarious patients, few (if any) practitioners who are experienced in tropical practice believe that this is a common cause, because, while they are in the habit of prescribing quinine in large doses for all varieties of the malarial fevers, they do not practically find that blackwater fever is a strictly localized disease, and that there are some malarious districts in Africa which are free from it."

Cancer in Germany.—The steady increase of malignant disease is the dark shadow on recent medical progress. In Germany and England, where the only exact statistics are available, cancer increases *pari passu* with the decline of consumption. Thus, in the former country, the annual increase of the disease is estimated by Dr. Maeder (*Zeitschrift für Hygiene und Infections-Krankheiten*, xxiii., p. 235) at 0.17 per 10,000 living. This will by the end of the century give a death rate of 22 per 10,000 which is the present consumption mortality of Germany. If by that time the tuberculosis rate is brought down to five, we may congratulate ourselves on having exactly reversed the proportionate destructiveness of the two disease. There is no reason, however, to suppose any connection between the corresponding rise and fall in the two diseases, for the unfortunate people of Saxony and Baden, though they share in the increase of cancer, have hitherto had no part in the decline of consumption. The fact most clearly brought out by Dr. Maeder's statistics is the influence of locality and of town life. Thus in Prussia cancer mortality in towns is more than double that in the country, being 7.9 compared with 3.8 in 1896, and the mortality in the large towns (over 100,000) is relatively greater than in the smaller ones. At the same time certain towns are specially afflicted, forming as it were cancer centres, while others are comparatively exempt. Thus there are relatively more than twice as many deaths from cancer in Stralsund and Schleswig as in Treves and Coblentz.

Medical Aspects of Life Assurance; Female Lives.—In the population at large, the average mortality for women (England and Wales 1861-90) is about 2 per 1,000 less than for men, a difference largely due to their protection from the occupation risks to which men are liable. This difference, however, is not equally distributed over the whole period of life, as between the ages of five and thirty-five years the mortality between the two sexes is nearly equal, while from ten to twenty years the deaths are more numerous among women. Among assured lives however, the reverse holds; instead of a less mortality, a marked excess of varying degree in different returns over the death rate among men is found up to the age of forty-five to fifty years, due partly to incomplete medical examination, partly to the motive for assurance. The increased mortality among women before twenty is largely due to phthisis, which has an earlier age incidence among women than among men, and from the early age has a little interest for assurance purposes. After twenty the increased mortality among women arises from the accidents of childbirth. "Between the ages of twenty-five and forty-five childbirth accounts for nearly 1 in 10 of the total deaths of women, and if the deaths from this cause were removed, the mortality would fall well below that of men" (Hingston Fox). In the general population the percentage of deaths is about 1 in every 200 labors, but for the first labors 1 in 100, or double. Not only is the mortality of childbirth greater for primiparæ, but it is influenced also by the age of the mother. Matthews Duncan states that the age of least mortality is near twenty-five, increasing gradually on either side this age, being 3 per cent. between nineteen and twenty-six; 9.75 per cent. between thirty-six and forty-five. Just as the general mortality is greater among assured women, so the risk of childbirth increases 34 per cent. (H. Fox), the explana-

tion probably being that many of the policies are entered into for this very contingency. Childbirth, then, especially for primiparæ, constitutes such an element of danger, that it must be met by some charge, and this is usually done, a common practice being to make an extra charge of 5*s.* ($1.25) per cent., ceasing at fifty, or a single extra charge of 15*s.* ($3.75) to 20*s.* ($5) on the newly married or those pregnant for the first time. Hingston Fox recommends the following rates: (*a*) If one or more children without difficult labors, accept; (*b*) if difficult labors, accept at an advanced premium; (*c*) if no children and within three years of marriage, accept with a single extra charge; if under twenty or over thirty, postpone till after confinement, because of the high risk. The question of childbirth is the most important in female lives. Other considerations are marriage. The death rate for married women is less than for the unmarried, except at the ages when the risk of childbirth is highest. In phthisis in women, inheritance has a greater influence than in men, but there is much discrepancy of opinion as to the exact proportion. Phthisis also runs a shorter course in women than in men by one and a half to two years (Williams), and appears earlier, there being a marked preponderance in females up to thirty-five, and this incidence is strongly marked from the age of puberty upward, the mortality running very high from fifteen to thirty-five; after forty-five it rapidly declines. In cancer, Dr. Payne concludes that the risk is greater in females, the death rate being higher, the liability being noticeable earlier, even in the decade from twenty-five to thirty-five; the maximum liability is earlier, from forty-five to fifty-five, as against that from fifty-five to sixty-five, and the total period of liability is longer. The evidence of heredity is also much stronger in females than in males. There is also a special risk in them from the frequency with which cancer of the breast (and probably also of the uterine organs) is transmitted by inheritance. He sums up by concluding that the death of the mother requires a substantial addition; if one other female relative has been affected, the risk becomes serious, and in some cases prohibitive. The death of a male relative from cancer is less serious, but no female life with a well-established history of cancer should be accepted at the ordinary rate. Hence an even more careful inquiry into the family history is needed than in the case of men. Hernia requires an advance—if umbilical it is a bar.—Dr. Perkins in February *Practitioner.*

Milk as a General Antitoxic.—A universal antitoxic, applicable to most cases of poisoning, has often been demanded. One exists, and it is very simple and well known, the *Practical Druggist* asserts. This universal antidote is cow's milk. Milk, by its fatty matter (butter), and by its casein, protects the mucous membrane against the corrosive action of acids, alkalies, and other caustic or irritant substances. The chemical rôle of casein is here very remarkable and very valuable. It is able to fill the double part of acid and of base, in presence of compounds with which it is brought into contact. It not only coagulates under the action of acids by combining with them, but it also yields a precipitate with most mineral bases, forming insoluble caseates. If precipitation does not immediately take place with a product having a given reaction (acid or basic), this precipitate will appear through the intervention of another substance of contrary reaction. This is a very important law in toxicology, which, as has been observed by its discoverer, Dr. Crowzel, has never before been formulated or even noticed. This chemist, therefore, proposes to add to the milk five per cent. of borate of sodium. This salt is not toxic and is employed because it precipitates as insoluble borates all the mineral bases, except harmless or slightly poisonous alkaline bases. The poisonous acids decompose it, seizing on the sodium and setting free boric acid, which is less poisonous and less soluble. Borate of sodium thus realizes very remarkable general conditions, which are sufficient to make it a general antidote, although unfortunately not a universal one.

Statistics of the Medical Profession in Germany.—Dr. Schwalbe's "Medical Directory" for 1901 has just appeared. The statistics in this valuable book show that the number of medical men in Germany has again increased, being now 27,374, or 2.6 per cent. more than in the previous year. In 1899 the increase was 3.6 per cent.; between 1894 and 1898 it was from 3.6 to 3.9 per cent. In Prussia there are 16,498 medical men, in Bavaria 3,036, in Saxony 2,048, in Wurtemberg 881, in Baden 1,087, in Hesse 683, in Alsace-Lorraine 683, and the remainder in the other states of the empire. In 1900 there were 5.24 medical men for each 10,000 inhabitants, the proportion being 5.11 in 1899. On an average 5.06 medical men resided in an area of 100 square kilometres (38 square miles) in 1900, and 4.94 in 1899, but this number varied very much in the different parts and provinces of Germany. In Saxony, for instance, there were 13.66 medical men; on the above area in Prussia 4.73; and in Bavaria 4. In several districts of Prussia the proportion was exceedingly small, being only 0.99 in the district of Cöslin and 1.11 in the district of Gumbinnen. Also in some districts of Bavaria there were only 1.68 medical men on 100 square kilometres. As to the great towns, Berlin has 2,360 medical men, as compared with 2,314 in the previous year, being one medical man for each 798 inhabitants; Munich has 694; Hamburg, 555; Breslau, 545; Dresden, 428; Leipsic, 416; Cologne, 338; Frankfort, 334; and Strasburg 213. The above statistics have been published by Dr. Heiman in the *Deutsche medicinische Wochenschrift.*—*London Lancet.*

Infantile Tuberculosis.—In the discussion at the Paris International Medical Congress on this subject, Hutinel dealt with the problems of heredity and said: "If there be anything in immunity, there ought to be an attenuated form of inherited tuberculosis which should render its possessor proof against infection. This inheritance would differ radically from inheritance of a predisposition to the disease. These two forms do not necessarily exclude each other." Moussous, referring to clinical forms, mentions the following: 1. Acute general tuberculosis. 2. Chronic general tuberculosis, which includes the diffuse forms of Aviragnet, and the apyretic form of Marfan, both of which represent a cachexia. 3. Many local types, such as general maldevelopment, adenopathy, tuberculous meningitis, etc. Richardière also spoke of clinical forms, giving as his opinion that "in the young child, tuberculosis is practically a general disease. A state of general bacillosis may be seen even without the formation of tubercles. In these general types some one organ may predominate in symptomatology, but the disease is not actually localized as in the adult. Generalization of the disease from the primary focus appears to be the rule in infancy, and this trait gives to the malady its altogether fatal character."

Etiology of Dysentery.—Dr. Simon Flexner sums up the present knowledge of the cause of dysentery as follows: 1. No bacterial species yet described as the cause has an especial claim to be regarded as the chief micro-organism concerned with the disease. 2. It is unlikely that any bacterial species that is constantly and normally present in the intestine or in the environs of man, except where the disease prevails in an endemic form, can be regarded as a probable cause

of endemic dysentery. 3. The relations of sporadic to epidemic dysentery are so remote that it is improbable that the two diseases are produced by the same organic cause. 4. The pathogenic action of the amœba coli, in many cases of tropical and in certain examples of sporadic dysentery, has not been disproved by the discovery of amœbæ in the normal intestine and in diseases other than dysentery. While amœbæ are commonly present, and are concerned in the production of the lesions of subacute and chronic dysentery, they have not thus far been shown to be equally connected with the acute dysenteries, even in the tropics. In the former varieties, bacterial association probably has much influence on the pathogenic powers of the amœbæ.

Philanthropy and Scientific Medical Progress.—The following extract from the annual report of Mr. Isaac Wallach, president of Mount Sinai Hospital, is of interest as showing how philanthropic endeavor keeps pace with scientific medical progress: "The nineteenth century has been richer in the advancement of science and civilization than any other which has preceded it. In medicine it has produced anæsthesia, bacteriology, bloodless operating, antisepsis, antitoxin therapy, and the Roentgen rays. During this period, benevolence has fully co-operated with science. In all communities, notably in ours, the well-to-do have evidenced a higher and nobler conception of their obligation toward their less fortunate fellow-men, and have freely shown a readiness to devote their wealth to the development of science, the application of medical skill for the sick poor, and to the support of philanthropic institutions in general. This generosity has manifested itself particularly in the founding and maintaining of hospitals, and it is a noteworthy fact that of the one hundred and five general and special private hospitals and dispensaries in this city, with but two exceptions, all have been brought into existence during this era. Of this number, twenty-eight were established from 1850 to 1870, and sixty-six from 1870 to 1900, showing that seven of these medical institutions were founded in the first half and ninety-six in the latter half of the nineteenth century. From this it may be justly concluded that the charitable tendencies of our citizens have been equal to the growing needs of our community."

The Metric System.—The *Manufacturer* quoted by the New York *Evening Sun*, says: "It looks as if Congress at last is going to go on record for giving the country an indication of far greater intelligence than is usually put down to the credit of that body. It is to pass a law making the metric system the standard of weights and measures. Anent this bill, we have read in technical papers some editorials that rank for linguistic, almost logarithmic density with any ever furnished for the fund of involuted absurdity by Mark Twain at his best. One paper talks of Germany still using Whitworth and Stubb wire gauges 'for the simple reason,' it says, 'that aliquot even subdivisions, according to the multiples of two, using the inch as a standard of length, seem to come out nearer what is desired in practice than decimal multiplication or subdivision of any of the metric units, so far attempted.' What does that mean? Does the metric system do away with two or one, or any unit? Germany keeps the Whitworth and Stubb, because it bought them so long and sticks to them so close that it cannot or will not give them up. But for the one argument against the metric system in this country, Germany had thirty. There was a different kind of measure in thirty different parts of the Empire. If we are wise we will not neglect a system almost universal, and sure to be, in its use. It is all nonsense to say our people will be bothered by terms. It is as easy to learn the names in the metric system as in any other. If a kilogram is a trifle more than two pounds, half a kilogram is a trifle more than a pound. A metre is thirty-nine inches, an inch is a thirteenth of a foot, where now it is a twelfth. A mile is a thousand time a metre or a thousand times three thirteen-inch feet. Why was twelve inches called a foot? It is no harder to think of a thirty-nine-inch standard, than a thirty-six inch one. If we adopt the metric system, we will win our way easier in foreign markets. If we don't, we won't. That is reason enough for its adoption. By adopting the metric system, we only put ourselves in line with most of the world. England and we are the only nations not under this most sensible of all systems. Like it or lump it, if we are to hold our own, to say nothing about making gains in foreign markets, we shall have to go over to decimals in weights and measures. It will pay, too. For the dollar lost by doing so, thousands will be lost by delay. The commerce of the world will be carried on in decimals. When one thinks of what it meant to Continental Europe to give up their old systems for the metric, we can hardly help laughing at the lame or limping excuses given here and in England for not adopting it. A good and wise way to begin the twentieth century would be to adopt the metric system."

Malaria on the West Coast of Africa.—Dr. Hans Ziemann, late government physician in Cameroon, published in the *Journal of Tropical Medicine*, January 1 and 15, 1901, an exhaustive study of the above subject. Referring to the clinical features of the tropical fever of the Cameroons, he says: "During my last service on the West coast, with the exception of the parasites of tropical fever, I never saw quartan parasites in white people, only tertian parasites, and these only in Cameroon, and even there only on three occasions. Koch, in East Africa, found the tertian parasite in ten per cent. of all cases of fever; in Cameroon I found the same only in 1.1 per cent. of the cases. This difference is exceedingly remarkable, and signifies, in other words: In Cameroon the clinical feature of malaria is dominated almost exclusively by the tropical parasite. In negroes in Cameroon and Victoria I also found only the parasite of tropical fever."

Treatment of Typhoid and Dysentery in South Africa.—Dr. Ryerson, who has recently returned from serving with the Canadian volunteers of the British army in South Africa, gave an interesting address in Toronto on his experiences, a short time ago. Speaking of the treatment of typhoid, he said it was practically the same in the British army in South Africa as in Toronto and everywhere else. Disinfection of the bowel either by means of boric acid taken internally or of enemata was considered in many cases to be remarkably successful. Another form of treatment was that of starvation. The patients were starved for seven or eight days. He considered that in some cases it might be dangerous, because a number of men were exhausted when brought in. Nothing whatever to eat was their treatment, nothing at all except water, and all of that they could drink. The medical officer in charge of these cases, and under whose supervision this plan of treatment was carried out, informed Dr. Ryerson that he had fewer deaths than in any other hospital in Bloemfontein.

Want of Medical Officers in the Philippines.—The scarcity of medical officers in the Philippines, since the first days of occupation to the present moment, has been the greatest source of anxiety that has confronted the various chief surgeons. At the present time this scarcity is more apparent than it has ever been, and, roughly speaking, 10,000 troops are

serving at posts with practically no medical attendance. The number of posts in the Philippine Islands is now 375 and is constantly increasing. To fill these posts there are only 336 medical officers now on duty in the islands. Of these 336 officers, 103 are detailed for other duties, leaving an effective force of 233 men to supply 375 posts. As an actual fact, there are at present [August 10, 1900] over 400 posts, and the medical force has been reduced by four. . . . In time of peace in the United States there were, roughly speaking, 20,000 troops and 180 medical officers, which gives 111 men to each surgeon. In the Philippines there are 336 medical officers and 63,000 men, or 187 men to each surgeon. A total of 500 medical officers is needed properly to care for the present number of troops in the Philippines.—Extract from annual report of Colonel Charles R. Greenleaf, chief surgeon, division of the Philippines.

Health Reports.—The following cases of smallpox and yellow fever have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 9, 1901:

		Cases.	Deaths.
Smallpox—United States.			
Alabama, Mobile	February 23d to March 2d	..	1
California, San Francisco	February 18th	8	
District of Columbia, Washington	February 25d to March 2d	7	
Florida, Jacksonville	February 23d to March 2d	3	
Illinois, Cairo	February 16th to 23d	6	
Iowa, Ottumwa	February 2d to 9th	1	
Kansas, Lawrence	February 23d to March 2d	2	
Wichita	February 23d to March 2d	12	
Kentucky, Lexington	February 23d to March 2d	2	
Louisiana, New Orleans	February 23d to March 2d	7	2
Michigan, West Bay City	February 23d to March 2d	5	
Minnesota, Winona	February 23d to March 2d	12	
Nebraska, Omaha	February 22d to March 1st	5	
N. Hampshire, Manchester	February 23d to March 2d	27	
New York, Elmira	February 23d to March 2d	1	
New York	February 23d to March 2d	64	11
Yonkers	February 22d to March 1st	1	
North Carolina, Charlotte	February 1st to 28th	16	
Ohio, Ashtabula	February 23d to March 2d	2	
Cincinnati	February 22d to March 1st	2	
Toledo	February 23d to March 2d	8

Yellow Fever.			
Cuba, Havana	February 17th to 24th	..	3

The Bacillus of Influenza.—The influenza bacillus is found chiefly in the expectoration, especially in the tough, yellowish-green pus discharged in cases of influenza bronchitis. It is found in this pus both within and outside of the pus cells, the intracellular distribution occurring particularly in the late stages of the disease. It is also found in the nasal discharges in some cases in enormous numbers, and may be found in the discharges from other mucous surfaces communicating with the air passages, as the accessory nasal cavities and the middle ear. The morning sputum is especially to be recommended for examination, according to Pfeiffer. The organism is not, as a rule, found outside the respiratory tract. Since Pfeiffer's original article was published, the great majority of writers agree with him in stating that the disease is essentially a toxic one. Thus Weichselbaum, Huber, Voges, Mossé, Pfuhl, Borchardt, and other careful observers all failed to isolate the organism from the circulation, after numerous attempts. That the organism can occasionally occur outside the respiratory system and its annexes is shown by its isolation from meningeal exudates by Pfuhl, Haedke, Cornil, Durante, and others, and its occasional isolation from the spleen.—George Blumer, *Albany Medical Annals.*

Injury to the Earning-Capacity of the Individual from Partial or Complete Loss of Vision.—Dr. Howard F. Hansell, of Philadelphia, writing on the above subject in the *Annals of Ophthalmology* for October last, concludes as follows: "Blindness is that degree of loss of vision that incapacitates one from earning his living in any occupation requiring the use of the sense of sight, the degree varying according to the demands of the occupation. Vision of less than one-half diminishes the earning-power, and the less the vision the greater the loss of earning-power. Monocular blindness is not incompatible with full earning-capacity. Monocular blindness and weak sight in the remaining eye rapidly diminish the earning-power. The loss of earning-power owing to defective vision may be computed according to a simple system based upon the ratio of the loss of vision to the full earning-capacity at any age and in most occupations."

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

REMARKS CONCERNING OPERATION IN CASES OF TYPHOID FEVER WITH INTESTINAL PERFORATION.

BY A. A. BERG, M.D.,

ADJUNCT SURGEON TO MOUNT SINAI HOSPITAL.

CASE I.—Ambulatory typhoid fever in a boy seven years old; perforation of an ulcerated Peyer's patch, with extravasation; diffuse sero-purulent peritonitis; laparotomy; suture of the perforation twenty-two hours after rupture; recovery. Joseph H——, admitted to the surgical service of Dr. Gerster, August 18, 1900, with the diagnosis of diffuse peritonitis following appendicitis. The boy was admitted at 10 o'clock P.M., the mother giving the following history. The child had had no previous illness. The present sickness had commenced about a week previously, with headaches and general lassitude; there had been no abdominal pain. The bowels had moved regularly, and the stools were normal. There had been no fever, and the child had not been in bed at any time, but continued playing about. In the early morning of the day of admission, the child complained of violent cramps in the lower part of the abdomen and in the right iliac fossa. There was no collapse at the time of or following the cramps. There had been one normal stool after their onset. During the day the child had several chills followed by fever, and vomited once.

Physical examination revealed a well-nourished boy, with a temperature of 103°, pulse 136, and respiration rate of 26. The heart and lungs were normal. The abdomen was extremely distended and everywhere very tender, but especially so in the right iliac fossa. The abdominal walls were rigid. There was slight dulness to percussion in the flanks. Per rectum there was slight bulging of Douglas' cul-de-sac, but no inflammatory mass could be made out. The tongue was dry and coated. There was no eruption. The liver and spleen appeared to be normal in size, but the extreme abdominal distention masked the flatness usually obtained over these viscera.

Immediate operation was decided upon and accordingly at 12 o'clock midnight, about twenty-two hours after the acute onset in the morning, under chloroform anæsthesia I opened the abdomen in the right iliac region by the Kammerer incision. There was at once a discharge of sero-purulent material from the free peritoneal cavity. The peritoneum was everywhere intensely injected, and no limiting adhesions were present. The peritoneal lymphatic glands were enormously swollen, some of them being the size of walnuts. The appendix was at once sought for, and readily found in the right iliac fossa; to all appearances it was normal, except that its peritoneal covering shared in the general injection. Its mesentery was secured with a ligature, and the organ itself ligated and ablated. It was quite evident that the appendix had not given rise to the intense peritonitis and lymphatic enlargement that was present, so further search was instituted for the cause. All of the small intestines were much injected and in part dilated. As the intestines were being rapidly passed through the fingers, an enlarged and especially prominent Peyer's patch, low down in the ileum, came into view, and in its centre was a perforation about the size of a millet seed. From this perforation a thin, yellowish-white fluid was discharging into the peritoneal cavity. The perforation was at once closed with a double row of Lembert sutures of silk, so that the entire Peyer's patch was covered by the adjacent intestinal wall. Further search for additional perforations being negative, the abdominal cavity was sponged dry with sea sponges, and a narrow wick of gauze passed down to the appendicular stump, to protect its raw surface. The rest of the abdominal wound was closed by through-and-through sutures. The child collapsed during the progress of the operation but responded nicely to stimulation.

Subsequent history. The child reacted well from the operative attack; during the nine days following the operation the temperature ranged from 100° to 104°, the pulse being 120 to the minute. The bowels moved on the second day and thereafter daily. The stools were not typhoidal in character. There was considerable abdominal distention but no roseola; no Ehrlich reaction was obtained in the urine, which was otherwise also normal. The gauze wick was removed from the abdomen after forty-eight hours. On the sixth day, the wound was again dressed, when all the stitch holes were found to be infected. After the ninth day the temperature became and remained almost normal, likewise the pulse rate. The Widal reaction remained negative up to the nineteenth day of his stay in the hospital, when the assistant pathologist, Dr. Libman, reported it to be positive. Again on the twentieth day the Widal test was reported positive, with a dilution of 1:40. The stitch-hole infection retarded the closure of the abdominal wound; otherwise convalescence was uninterrupted and the child was discharged cured October 10, 1900.

Comments. This case presents many interesting points for consideration.

First, as to diagnosis. When the child was admitted to the hospital, the intense peritonitis which was present so clouded all the other symptoms that no conclusion could be arrived at as to the cause of this inflammation of the peritoneum. If we ask ourselves whether the diagnosis could have been made at an earlier period, we must answer in the negative, as will appear from the following considerations. The child, although complaining of headache for a week previous to the acute onset, had not been confined to bed. The onset was sudden; there were no other indications of typhoid. Even had the latter been thought of by the physician, it often enough happens that the

[1] These cases were reported to the New York Academy of Medicine, surgical section.

ulcerations affect the mucosa of the appendix, and perforation of one of these ulcerations is certainly possible. In this boy the symptoms pointed to an acute peritonitis resulting from a perforation of some part of the intestinal tract; the localized pain in the right iliac fossa indicated the appendix as the most probable site of the perforation, and in the absence of any signs suggesting typhoid fever, the perforation resulting from an ulcer due to this cause could not be considered.

As regards the treatment of the peritonitis. In a paper on the peritoneum and the treatment of diffuse exudative peritonitis,[1] I have called attention to the fact that the peritoneum when physically unaltered, even though it is the seat of intense inflammation, possesses in its rapid resorptive power an attribute by which it can efficiently protect itself against the local action of bacteria, and amply provide for a removal of an exudate that may be present within its cavity. This important consideration, together with the serious and even fatal objections to drainage, have led me, when the peritoneal membrane remains smooth and uncovered by fibrin or granulations, entirely to do away with drainage, and to close up the abdominal wound. When, however, a region had been denuded of its peritoneal coat, or when the peritoneum, though intact, had become modified in its physical character through traumatism or inflammation, then all such parts of the peritoneum must be drained, and thoroughly drained, for they no longer possess the rapid resorptive power of physically unaltered peritoneum, and hence its protective and auto-drainage attributes. So in this case, as the peritoneum was smooth although intensely injected, I determined to close the abdominal cavity, merely protecting the raw appendicular stump with a thin gauze wick. True to my expectations, the peritoneum protected itself admirably from the multitudes of bacteria which were present in its cavity, and likewise provided for the removal of the exudate. But, and this is a very important point, the cellular tissue of the abdominal wall, which does not possess the attribute of rapid resorption that belongs to serous surfaces, was unable to withstand the local action of the bacteria which had wandered into it through the stitch-hole openings in the peritoneum, and infection with pus formation took place in the abdominal wound.[2]

Case II.—Traumatic rupture of the intestine, at the duodeno-jejunal junction, diffuse sero-purulent peritonitis; laparotomy twenty-six hours later; suture of the ruptured intestine; nine days later symptoms of intestinal obstruction; laparotomy; obstruction, due to adhesions, relieved; recovery. Samuel M——, ten years old, admitted to the surgical service of Dr. Gerster, at 8 o'clock on November 18, 1900. His history was as follows: At about seven o'clock the previous evening, while playing in the street, he had been run over by a coal cart, the wheel passing across the abdomen in the hypochondriac regions. He was able to get up immediately after the accident, but had such severe abdominal pain that he was scarcely able to walk home. He did not vomit until after the administration of medicines later in the evening. A cathartic that was given to him was retained, but did not produce any movement. An enema administered to him the following morning was thought by the mother to have been slightly effectual. The child had no chill; possibly had some fever. The boy says he had had his dinner, consisting of chicken, and bread and coffee, about one hour before the accident.

Physical examination on admission showed a well-nourished boy, with a temperature of 101° F., pulse rate of 116, respirations 36; the heart and lungs were normal. The abdomen was distended, and everywhere rigid and tender. There was tympanitic resonance over the entire abdomen, except between the left free border of the ribs and the umbilicus, where the resonance was dull tympanitic. There was a shifting dulness in the flanks. The hepatic and splenic flatness was almost completely obliterated. In the region between the left costal margin and the umbilicus an indefinite mass was to be felt, and here the tenderness was more marked.

The diagnosis of rupture of the intestine with diffuse peritonitis was made, and immediate laparotomy proceeded with. At about 9 o'clock P.M. the writer opened the abdomen in the median line between the costal angle and the umbilicus. The intestines were seen to be moderately distended and injected, and free sero-purulent, non-fetid fluid was present in the peritoneal cavity. The small intestines were gradually withdrawn from the abdomen, examined, and at once covered with hot towels and supported by an assistant, so as to prevent traction upon the mesentery. Some fresh fibrin was seen along the upper coils of the small intestines, and just at the duodeno-jejunal junction was found a rupture. This rent ran almost at right angles to the long axis of the bowel, occupied the right side of the intestine, was three-quarters of an inch long, and its edges gaped apart about one-third of an inch. The rent also extended into the mesentery of the jejunum. There was no hemorrhage from the torn edges of the ruptured intestine, the mucosa pouted into the margins of the opening, and there were escaping some coagulated albumin and yellowish-green fluid. No further lesions of the intestine or other viscera were found.

The opening in the bowel was closed by three rows of sutures, the first a Czerny of the mucosa alone, the other two Lembert. The rent in the mesentery was closed by a single row of interrupted sutures. The eviscerated intestines and peritoneal cavity were cleansed with hot saline solution, the intestines were replaced, a thin protective strip of gauze was passed down to the suture line in the intestine, and the abdominal wound was closed by through-and-through silkworm-gut sutures. The child required free stimulation toward the close of the operation.

Subsequent history. The child reacted well. The pulse rate after the operation was 148; temperature, 101°; respirations, 24. Nothing was allowed per os for forty-eight hours, nourishment and stimulation being given per rectum. The boy vomited once on the second day. The pulse gradually diminished in frequency and its quality improved. The bowels moved by enema on the second day, and daily thereafter until the ninth day. The gauze wick was removed on the second day. On the fifth day a stitch-hole infection was noticed. The boy was convalescing nicely until the eighth day. On this day he complained of considerable abdominal pain, which was thought to be due to the infection of the abdominal wound. On the ninth day the boy vomited once, but his bowels moved by enema. The pain continued, and the boy looked bad. The next day the child's condition was worse. His bowels could not be made to move, the vomiting persisted, the material ejected consisted of bile and

[1] Medical Record, June 30, 1900.

[2] This stitch-hole infection occurred in other cases of diffuse peritonitis treated in a similar manner; in the second case reported in this paper, the stitch-hole infection led to an adhesive peritonitis with secondary intestinal obstruction. In another case it gave rise to a very severe phlegmon of the abdominal wall, which resulted in a reinfection of the peritoneum on the fourteenth day after operation, to which the patient succumbed. I have abandoned, therefore, the through-and-through sutures of the abdominal wall, and close only the peritoneum with a catgut suture, leaving the outer wound open; or simply place a gauze diaphragm, lined on its under surface by a sheet of rubber tissue held in place by a few silk sutures, over the intestines, within the edges of the abdominal wound, and pack the outer wound. A detailed report of the seven cases of diffuse purulent peritonitis, treated without drainage, will shortly appear.

mucus. The pulse rate was rising, the temperatures were 99°–100° F. I felt some hesitancy in again opening the abdomen and decided to wait another twelve hours. On November 29th, the eleventh day after operation, the conditions becoming rather worse and the bowels not moving, I decided on a second laparotomy, expecting to find a band constricting the intestine, or possibly a contraction of the intestine at the site of the rupture, although the latter appeared to be hardly possible.

Second operation, November 29, 1900. Median laparotomy through former incision; adhesive peritonitis found as cause of the obstruction; separation of the adhesions; closure of abdominal wound by gauze diaphragm lined with rubber tissue. Under nitrous-oxide anæsthesia, I first thoroughly curetted the abdominal wound, so as to remove as far as possible the infected tissues. The small intestine was firmly adherent to the edges of the abdominal wound, and the coils of intestine in the vicinity were densely adherent to each other; the adhesions causing several acute kinks in the bowel. These adhesions were all carefully separated with very little hemorrhage, although the serous coat tore away from the intestine in several places. It was replaced by a few sutures of fine catgut. Further exploration revealed a dense band of adhesions along the track of the gauze strip which had been passed down to the site of the rupture at the time of the first operation. These adhesions had also kinked the jejunum a few inches below the fossa of Trites. After all the adhesions had been separated, the intestine was cleansed and replaced into the abdominal cavity and retained in place by a diaphragm of gauze, lined on its under side by a single layer of rubber tissue which was secured to the gauze by a few silk sutures. (The object of the rubber tissue was to prevent new adhesions from forming.) A dry aseptic dressing was applied. It was quite evident that the adhesive peritonitis had started at the infected abdominal wound, and the abdominal wound had in turn become infected from the pus within the abdominal cavity at the time of the first operation.

Subsequent history. The child collapsed toward the end of the operation which had lasted only about twenty minutes; but under hypodermic stimulation he reacted nicely. One hour after the operation he was given a series of salts which were retained. Twelve hours later the bowels were moved by enema. From then on the child's condition improved: the bowels moved daily; nourishment was liberally taken. The gauze diaphragm was removed on the sixth day, and the wound then packed. There was uninterrupted subsequent recovery; closure of the abdominal wound occurred by granulation, and the boy was discharged cured January 16, 1901.

Concerning Operation in Cases of Perforation of a Typhoid Ulcer.—No more important subject has been submitted to the internist since the new era of abdominal surgery than the question of whether or not to submit a patient suffering from an intestinal perforation in the course of a typhoid fever to an operative procedure. Ever since the first successful suture by Mikulicz of an intestinal perforation resulting from a typhoid ulcer, the surgeons have asserted that patients in whom this complication has developed should be at once submitted to them for repair of the perforation, whereas the practitioner has as steadfastly maintained that operation holds out to these unfortunate patients no better hope for recovery than does expectant medical treatment; first, because typhoid patients already debilitated by a long and exhausting disease stand operation very poorly; and secondly, because nature in a certain proportion of cases walls off the perforation by protective barriers of adhesions, and so guards the patients from a diffuse septic peritonitis. It is the duty of the surgeon, then, to meet the internist on both these disputed points, clearly stating what has been the past experience as regards the dangers of operation during the course of a typhoid fever, and what is the danger of delay in a case of ruptured ulcer with extravasation of intestinal contents into the peritoneal cavity.

A. Dangers of operation in typhoid patients. The best idea as to how patients suffering with a typhoid fever bear operative attacks can be obtained by consulting the reports of those who have operated upon patients in this disease. In the last sixty-six cases collected by Keen[1] of typhoidal perforation of the intestine subjected to surgical interference, we find that twenty-three died within the first twenty-four hours following the operation. Of these twenty-three patients, seven were "in extremis" at the time of operation, and surgical interference had probably been undertaken only as a desperate hope of saving a positively forlorn case; one died of a septic inhalation pneumonia from the aspiration of stomach contents in the air tubes during the anæsthesia, one of an unexplained toxæmia, eleven of diffuse septic peritonitis which had been in existence before the operation, and only three are reported as having succumbed to the shock attending the operative attack. In two of these latter three there was present at the time of operation a diffuse peritonitis. If these statistics are compared with those obtained from reports of operation for diffuse peritonitis due to other causes, *e.g.*, appendicitis, in patients not suffering from a long-continued fever, it will be seen that they do not differ materially, as fully one-third of the deaths in these cases occur within the first twenty-four hours, and fully as many as five per cent. die from the shock attending the operation.

The writer's personal experience as to how major operations are borne by typhoidal patients extends over three cases. One of these was operated upon by Dr. Gerster, and the other two were operated upon by himself. Dr. Gerster's patient was a woman in the second week of a rather severe typhoid fever, in whom the ulcerations involved the mucosa of the appendix and threatened perforation. The operation of appendectomy, performed at the German Hospital under general anæsthesia, was remarkably well borne by the patient, the course of the typhoid was uninfluenced by the operation; the patient passed through the disease without any further complications and made an excellent recovery.

The writer's personal cases were: one a male child ten years of age, in the third week of a severe typhoid fever, in whom a perforation was suspected, and an exploratory laparotomy advised by the attending physician. The operation, performed under eucaine local anæsthesia, with the patient in an extremely drowsy and feeble condition, was excellently borne. Exploration revealing no perforation, the abdomen was at once closed. The child was not weakened, the pulse continued to be of the same force and frequency, and the patient convalesced after a long siege of typhoid which was complicated by a relapse. The second case was that reported in this paper. The operation, though rather prolonged, lasting about fifty minutes, was also well stood by the child—the reaction being prompt and good.

Considering that the operation for the successful detection and closure of the perforation or perforations is usually attended by more or less complete evisceration of the intestines, it is really surprising that so few deaths from shock have been reported. It only goes to show that the resistance of these patients to severe and rather prolonged surgical procedures is

[1] Reported to the New York State Medical Association, October 25, 1899.

fully equal to that of other patients who are obliged to undergo similar operations. There can be only one serious objection to an abdominal operation, and that is the necessary suspension of the cold plunge baths. But a patient in whom an intestinal perforation is suspected or does exist, is never subjected to plunges, so that even this objection does not weigh against the carrying out of an abdominal section. The practitioner is to-day confronted with the results of the medical and surgical treatment of intestinal perforation occurring in the course of typhoid fever; and the surgeon must confess that the difference in cures is not very marked; but this is because the surgeon's aid is too often invoked when not only the perforation but also a diffuse septic peritonitis is present. The reason the operation is thus delayed is partly that the physician fears that the already enfeebled condition of the patient will render a succumbing to the operation a very likely result. Early surgical intervention will show between nature's and man's surgical efforts such a marked difference in favor of the latter that the question as to the propriety of operating for intestinal perforation with extravasation, occurring in the course of typhoid fever, will soon be settled, beyond the shadow of a doubt, in favor of it.

B. The dangers of delay in intestinal perforation with extravasation. The expectant method of treatment of typhoidal perforation of the intestine attended with extravasation, depends solely upon the surgical efforts of nature: upon the closure of the ruptured ulcer by adhesions to neighboring parts of the peritoneum or viscera. That such adhesions may form before perforation and remain intact, and so guard the patient from extravasation into the free peritoneal cavity, is certainly a possibility; but the waiting for these adhesions to form subsequent to perforation and thus limit or prevent extravasation is, in this era of abdominal surgery, entirely too uncertain to be relied upon.

It is this waiting upon the possibility of nature's spontaneous cure that is still keeping the mortality following surgical intervention so high; for the surgeon is too often consulted only when nature's efforts at repair have been found fruitless, and he is then called upon to deal not alone with a perforation but also with a septic peritonitis. This septic peritonitis is the danger of delay in intestinal perforation with extravasation. The mortality following operation for diffuse septic peritonitis due to other causes, *e.g.*, appendicitis, is about seventy per cent.; the mortality following surgical interference for perforated typhoidal ulcer attended with extravasation is about seventy-four per cent. If we wait with surgical interference until a diffuse peritonitis develops, we cannot hope, with our present method of treatment of diffuse peritonitis, to bring the mortality below seventy per cent. This frightful mortality must be weighed in the balance against early operation in patients who are mostly as well able to bear surgical attack as otherwise healthy individuals. If the question is viewed in this light it seems to the writer that there can scarcely be any difference of opinion as to whether early surgical intervention will be made use of, or reliance placed upon the uncertain and uncontrollable efforts of nature to close a perforation.

As to Operation in the Preperforative Stage.—The chief danger resulting from the rupture of a typhoidal ulcer of the intestine lies not in the perforation *per se*, but in the diffuse peritonitis that results from intestinal extravasation into the free peritoneal cavity. It is quite evident, therefore, that surgical intervention aiming at a closure of the perforation should be resorted to as soon as possible after the occurrence of such extravasation. This necessarily implies the establishment of an early diagnosis, and it may be stated as a rule that the prognosis will depend entirely upon the time at which a diagnosis is made and surgical intervention instituted. This at once suggests the possibility of operating before the perforation has actually occurred, in what Cushing has styled the "Preperforative Stage." The "preperforative stage," as defined by Cushing[1] (page 29), is "that whole period between the first involvement of the serosa with the customary formation of adhesions at that point until these adhesions, which may for a time constitute the floor of the ulcer after the serosa has given way, have themselves become broken down and general extravasation has taken place. This period, as in perforating appendicitis, may last a longer or shorter time and is associated with pain and tenderness and a possible rise in leucocytosis owing to the localized peritonitis." Here is a most important suggestion and one that demands the earnest consideration of the internist and surgeon.

It is certainly no uncommon experience for patients to develop at some time during the course of the typhoid fever all the clinical manifestations of a localized peritonitis. These peritoneal symptoms may arise from the stretching of the peritoneum by the swelling of the mesenteric glands, or from a chemical peritonitis due to the toxins of the typhoid organisms, or from an involvement of the peritoneum by contiguity in severe ulcerations of the intestines, that nevertheless never go on to perforation with extravasation. These are only a few of the causes other than impending perforation that may call forth symptoms of peritonitis. Do they mean that we are to interfere surgically? By no means and under no consideration. For, in most instances, these peritoneal symptoms subside spontaneously. Even granting that the peritoneal symptoms arise from an involvement of the serosa which covers a deep ulceration of a Peyer's patch, does this mean necessarily that this serosa will always give way and permit of extravasation into the free peritoneal cavity? Certainly not! How, then, can we think of interfering surgically for a perforation that does not exist, and which may never take place? If we knew in which ulcerations the serosa will undoubtedly give way and permit of extravasation, no one will dispute as to the advisability of opening the abdominal cavity, searching for these particular ulcerations, and covering them over with the adjacent intestinal wall. Quoting from the findings by Dr. Cushing at the first operation in his first case, "The last foot of small intestines showed several greatly thinned areas corresponding to Peyer's patches." Only one of these greatly thinned areas subsequently gave way and permitted of extravasation, and Dr. Cushing comments upon this subsequent perforation as follows (page 9): "It must remain undetermined whether this subsequent perforation was caused by the trauma inflicted upon the serosa covering this ulcer, by the gauze drain" which had been passed down to the site of a nearby perforation.

When our diagnostic acumen will have reached a higher stage of development so that we can differentiate the signs of local peritonitis as caused by an impending perforation from the peritonitis produced by other pathological conditions, and when we are able to foretell which serosa over a deep ulceration will give way, then certainly the preperforative stage of operation will be a reality. Until then we must agree with Cushing, when he says "that such symptoms of a localized peritonitis should put the attendant on his guard, so that the patient may be kept more than ordinarily quiet, and tubs omitted, especially if they are disagreeable and resisted."

With this conclusion the writer fully agrees; nay,

[1] "Laparotomy for Intestinal Perforation in Typhoid Fever." Johns Hopkins Hospital Bulletin, No. 92. November, 1898.

more, the surgeon should be consulted at this period, so that he may be ready, at the first sign of extravasation, to close the intestinal perforation. It is the intestinal extravasation that constitutes the grave danger of an intestinal perforation. I have no doubt that the local peritonitis, so often occurring in typhoid fever, is quite frequently due to a minute perforation which is effectually closed by a neighboring coil of intestine or viscus or portion of the abdominal parietes. These cases should receive the closest attention, and at the first sign of extravasation surgical interference should be made use of.

It is in this point of extravasation that the ruptured typhoid ulcer in the small intestine differs from a ruptured ulcer in the appendix. The appendix is a hollow tube communicating with the general intestinal canal by a comparatively small orifice. This orifice may be completely closed by even moderate swelling of the mucosa. When the communication of the appendicular cavity with the general intestinal canal is cut off. a rapid increase in tension of the confined contents within the appendicular canal takes place. This increased tension in itself leads to gangrene of the walls of the appendix, and when this has occurred the appendicular contents are forced out of the appendix with considerable pressure. This danger of gangrene and extravasation leads us to employ surgical aid for removal of the appendix as soon as there is any manifestation of a rise in pressure of the appendicular contents; for I maintain that the foudroyant character of the symptoms of an acute appendicitis is due to this increased tension within the appendix. In the intestinal canal, however, unless there is a paralysis of the muscular tunic of the bowel, a stasis of intestinal contents, and consequent increase of tension within the lumen of the bowel, does not occur. There is, therefore, no danger of gangrene resulting from increased tension, and furthermore, inasmuch as the direction of least resistance is practically at all times in the course of the lumen of the intestine, it is quite possible that neighboring adhesions will effectively close a minute defect in the substance of the bowel, especially if the defect has been slowly produced. I have no definite knowledge, how often such a natural closure of a minute defect occurs. But the presence of symptoms of a localized peritonitis, occurring in the course of typhoid fever, is no uncommon experience, and furthermore such a peritonitis most frequently goes on to spontaneous cure.

The comparison, therefore, between appendicitis and typhoidal ulcerations, as to operation in a preperforative stage, is not a good one, for the mechanical conditions which are present in the appendix, and which lend to an inflammation of this organ such a marked degree of intensity, with danger of gangrene and extravasation, do not at all obtain in the intestinal canal, unless a complete paralysis of the muscularis has taken place.

I would suggest, then, as regards the preperforative stage of typhoidal ulceration, that every typhoid patient who presents the symptoms of a local peritonitis should be most carefully observed by both the physician and surgeon, and at the very first indication of extravasation the surgeon should be prepared to open the abdomen and close the ruptured ulcer. This principle of action will save us from putting out a fire that has not commenced to burn!

Symptomatology and Diagnosis.—The early diagnosis of perforation with extravasation depends upon a complete and perfect understanding and recognition of the symptomatology. It will be noticed that the term perforation is always qualified by the writer with extravasation, first, because it is hardly possible that the symptoms that accompany perforation are due to the perforation *per se;* and secondly, because it is by no means proven that extravasation always follows perforation. I take the liberty, therefore, of suggesting the following consideration of the symptomatology of perforated typhoidal ulcer associated with extravasation.

A. Symptoms of the preperforative stage.

B. Symptoms at the time of perforation—(*a*) if with extravasation; (*b*) if without extravasation.

C. Symptoms of the postperforative stage.

A. The symptoms of the preperforative stage of typhoidal ulceration of the intestine are mainly dependent upon the involvement of the serosa which covers a deep ulcer. It is to be distinctly remembered that many cases never go on to destruction of this serosa, with the consequent perforation and probability of extravasation; but it is of the utmost importance to recognize this preperforative stage, so as to suspend tubbing, and be prepared to interfere surgically if actual perforation and extravasation occur. As indicated above, the symptoms of the preperforative stage are those of a localized peritonitis, and are: (*a*) Local rigidity of the abdominal wall. (*b*) Usually an increased leucocytosis. (*c*) Local pain and tenderness in the abdomen. (*d*) Possibly nausea and vomiting. (*e*) Possibly an increased rise in the pulse rate and temperature.

Of these symptoms the most important are the first two; all the other manifestations are variable, and simply strengthen a conviction afforded by the other two. Thus abdominal pain is often found in typhoid fever, without there being any involvement of the serosa; likewise nausea and vomiting may occur, without being due to peritonitis. But local abdominal rigidity and increased leucocytosis, occurring together in a typhoid patient, are of the utmost significance and should always put the attendant on his guard. For their detection it is necessary that careful and repeated examinations of the abdomen should be made, and that the leucocytes be counted at regular intervals of twenty-four to forty-eight hours. A leucocytosis may result from causes other than a localized peritonitis, but when it is associated with localized muscular rigidity of the abdomen it means a local peritonitis. If the other symptoms are present the diagnosis is strengthened. Too much stress cannot be laid upon the detection of these two signs—for this is the stage in which the surgeon should be asked in consultation; this is the time in which to make all necessary preparations for immediate laparotomy.

B. Symptoms of the perforative stage. These depend in almost all the cases upon the extravasation of intestinal contents into the free peritoneal cavity. With those rare exceptions in which a large blood-vessel of the intestine is eroded by the ulcer, and in which the signs of internal hemorrhage are consequently present, the perforation *per se* does not give rise to any symptoms. The clinical evidences that a perforation has occurred are due entirely to the intestinal extravasation, and are proportionate in intensity to the extent of the extravasation at the time of perforation. This is the reason why in some patients, *e.g.*, the case of the writer's, the symptoms of the perforation are comparatively insignificant, whereas in others they are of an alarming character. If the perforation is a small one, permitting of only a very slow leakage into the peritoneum, the reflex symptoms of shock, arising from the sudden soiling of this sensitive membrane, will be scarcely in evidence. If, on the other hand, the perforation is large, permitting of extensive extravasation, the reflex symptoms of shock will be very marked. The symptoms of this stage are entirely reflex in character, and are those of shock following upon extravasation; they are collapse, fall of temperature, cold clammy skin, rapid feeble pulse.

The writer would again call attention to the possibility of an utter absence of these symptoms, and in patients of this class it is absolutely impossible to make the diagnosis before the first symptoms of a peritonitis develop. In these patients it is especially important to have recognized the symptoms of the preperforative stage; for it is only by a comparison of the symptoms of this period with those that subsequently develop that an early diagnosis of peritonitis can be made.

C. The symptoms of the postperforative stage when extravasation has occurred are those of a progressive peritonitis. They may be summarized as follows: A disappearance of the leucocytosis; an increase in the local abdominal muscular rigidity; a rise of the temperature and pulse rate; nausea, vomiting, and increasing distention.

As mentioned above, there are a certain number of patients in whom a diagnosis cannot be established until the onset of an advancing peritonitis. It is especially in this class of patients, in whom the absence of the shock clouds the diagnosis, that it is important to detect the very earliest indications of a progressive peritonitis. These are the first two of those symptoms enumerated above. If these are recognized by the attendant the writer maintains that a diagnosis of the peritonitis can be made within the first six hours, which is early enough to save the majority of the cases by surgical intervention. Let us take for example a patient in whom the preperforative stage was well marked and recognized. A minute perforation has taken place, not associated with the symptoms of shock which would clearly indicate a perforation with extravasation.

If in such a patient the leucocytosis diminishes, and the local rigidity becomes marked and extensive, the presumption is very strong that an advancing peritonitis is present, and under such conditions, even if the evidence of a perforation is not absolute, an exploratory laparotomy is urgently and imperatively demanded. Cushing has explained the diminished leucocytosis as due to the great outpouring of leucocytes into the general cavity when a progressive septic peritonitis commences. Too much credit cannot be given to Cushing for calling attention to this diminished leucocytosis following upon perforation with extravasation.

When the other signs of peritonitis develop, the diagnosis cannot be any longer in doubt and the prognosis from any method of treatment is proportionally bad.

In concluding these remarks on the symptomatology I would say:

(*a*) That it is of the utmost importance to examine the abdomen frequently for evidences of local rigidity, and to make examinations of the blood every twenty-four to forty-eight hours.

(*b*) That in patients with a distinct preperforative stage the sudden appearance of the symptoms of shock clearly indicates a perforation with extravasation. It is to be remembered, however, that these symptoms of shock may be entirely absent, even though a perforation with gradual extravasation has occurred.

(*c*) That in patients with a distinct preperforative stage, a decreasing leucocytosis, and increasing abdominal rigidity, with or without the previous signs of collapse, indicate the earliest manifestations of a progressive peritonitis, and urgently demand immediate surgical interference.

In the above description of the symptomatology the writer has taken no notice of those patients in whom there is no preperforative stage. In such patients the diagnosis can be made in the second stage, provided it is marked, but if not we unfortunately have to wait until the peritonitis is established. In these patients, moreover, the earliest signs of the peritonitis are wanting, for we have no data of the preperforative stage with which to compare the earliest manifestations of a progressing peritonitis.

Time When to Operate.—It would seem reasonable that the time to operate was immediately after the diagnosis was established. This holds true with certain limitations. If the symptoms of shock are so very marked that the surgeon fears that the added shock of the operation will suffice to cause the death of the patient, it would be foolhardy to operate at once. In these cases the shock is for the time being a far more serious condition than the extravasation, and we must wait until the patient has rallied enough to enable him safely to withstand the added shock of an abdominal section and possible eventration. If the patient never rallies, as I have seen once, how uncalled for would be the efforts of the surgeon to close the perforation! It is impossible to formulate any rule as to how many hours after extravasation it is best to operate. The surgeon must decide in each case. Roughly speaking, the best time to operate is as soon after the extravasation as the patient can safely bear the shock of an abdominal section. This may be at once, or not before several hours, or even not at all.

Anæsthesia.—The writer sees no reason why a general anæsthetic should not be administered if the patient is in good condition. Certainly the surgeon can do his work better and quicker, and time is the most important essential in these operations. Furthermore, the symptoms of operative shock will be less, as a rule, when a general anæsthetic is used. For these patients must usually be eviscerated, and the straining and rigidity of the abdominal muscles under local anæsthesia necessitates the application of far more pressure upon the intestines to replace them within the abdominal cavity. If, however, the patient is in poor general condition, already exhausted by a long-continued febrile process, and has a rapid feeble pulse, a general anæsthetic is absolutely contraindicated, and the operation should be performed under a local anæsthetic and morphine.

For the treatment of the diffuse peritonitis see comments following Case I.

Conclusions.—1. The existence of typhoid fever does not contraindicate an operation; for typhoid patients bear operation almost as well as otherwise healthy individuals.

2. The repair of a ruptured typhoidal ulcer attended with extravasation should be undertaken as soon after the perforation as the patient can stand the necessary laparotomy and possible eventration.

3. Operation in the preperforative stage is not to be considered, for a local peritonitis does not always signify an impending perforation, nor does perforation always imply extravasation. As we have no means of foretelling which ulcers will perforate, an operation undertaken to forestall such a perforation is like putting out a fire that has not commenced to burn.

4. Extravasation can usually be early diagnosed if strict attention is paid to the recognition of the symptomatology.

Non-Absorbable Suture in Nephrorrhaphy.—The use of a non-absorbable suture for the fixation of the kidney has been objected to on the ground that it might lead to the formation of a stone in the kidney. This objection is purely theoretical, as no such case has been reported; moreover, it is contrary to the teachings of comparative pathology. The suture soon becomes encapsulated in a scar-tissue sheath, which, so far as the functionating structure of the kidney is concerned, makes the suture extrarenal.—Charles P. Noble, *Journal of the American Medical Association*, December 15, 1900.

CHRONIC GONORRHŒA AND MARRIAGE.[1]

By LUDWIG WEISS, M.D.,

NEW YORK.

THERE is still a controversy in reference to the time as to when the gonococcus should be looked upon as definitely extinct from the uro-genital apparatus. The whole question, which was discussed with such vehemence at the Sixth Congress of the German Dermatological Society at Strasburg, in 1898, is still unsettled. Upon one point all parties agree; namely, that the gonococcus must be destroyed, in order to effect a cure. While Behrend and his followers maintain that they can accomplish this by the use of astringents as of old, Neisser and his disciples have shown that the silver-salts (largin, protargol, etc.) are capable of annihilating the gonococcus with a certainty not achieved by any other known agent. But the whole question becomes a mooted one when the infectiousness of chronic gonorrhœa is considered.

It is self-evident that, as long as there are gonococci present, no matter how few in number, the discharge is infectious; but the matter becomes complicated when they reappear, after repeated painstaking examinations have failed to demonstrate their presence. The adnexa of the uro-genital apparatus furnish ample hiding-places for their continued propagation. These are the subepithelial and connective tissues, the lacunæ of Morgagni, Littre's glands and other follicular structures, the prostate, the seminal vesicles, and the efferent ducts grouped about the colliculus seminalis or caput gallinaginis. In few cases of gonorrhœa is the infection limited only to the anterior portion of the urethra or to its superficial structures. Such cases do exist, but unfortunately they are few. The path by which the gonococcus reaches the deeper structures is a wide-open one to its ingression. In its strife with the leucocytes, by invading them, and in its being carried off and toward the surface by the same power which it is bent on destroying, the gonococcus will, under certain conditions, settle itself in the deeper structures. The gonococcus has been regarded heretofore as chiefly an epithelial and intercellular parasite —one which thrives on the protoplasm of the leucocytes. Recent researches have shown, however, that it is not only capable of infesting the connective tissue, but that it may provoke suppuration there and be carried away bodily, so to say, by the blood and lymph channels, to remoter regions, causing veritable metastasis.

In chronic gonorrhœa, therefore, the habitat of the gonococcus will be found in the submucous and connective tissues and in the ducts of the different follicular structures. If we now subject the scanty surface discharge of such cases which show hardly any clinical symptoms to a microscopical examination, we will find mucus, muco-pus, epithelium in its different transition forms, bacteria, and sometimes a few ill-defined gonococci; but generally none at all of the last. We then pronounce the gonorrhœa cured, and the patient as not infectious. The fallacy of such an opinion may manifest itself in a shockingly surprising manner by causing a gonorrhœal infection in the female, or *vice versa*. Schiller, after examining three hundred women, maintains that when gonococci were present clinical symptoms were never wanting. Kollman has found gonococci in thirty per cent. of his cases of chronic prostatitis in which no clinical symptoms were evident. Kapitowsky, after examining one hundred prostitutes, found in eight per cent. of the patients gonococci in their cervical discharges. These women had been declared—clinically—recovered and had been discharged.

[1] From the forthcoming treatise on "Chronic Urethritis of Gonococcic Origin." Edited by Dr. Ludwig Weiss. William Wood & Co., New York. 1901.

Neisser has always claimed that gonococci may be present in the female genitalia, even when subjective symptoms and other microscopical signs are wanting.

These and kindred questions arise from the fact that in some continental countries the law provides a registration of prostitutes, a weekly medical examination, and gratuitous treatment in hospitals. The patients are discharged when a repeated microscopical examination fails to show the presence of gonococci. Although not belonging within the scope of this treatise, I must touch upon this subject, as the possibilities of the protean aspect of the gonococcus may, with some modifications, be applied to the male also. Besides, the life history of the gonococcus in the female is of more than paramount interest to us. The registering of puellæ publicæ, so alien to the American idea of consideration, even toward fallen women, only partly removes the opportunities of infection; while the greatest danger lies, in continental countries as well as in ours, in clandestine prostitution. Nothing short of educating the masses to the perception of the great social danger which lies in an attack of gonorrhœa, or legislation like that of the State of Michigan, will mitigate gonorrhœa's ravages, and save hecatombs of wrecked lives in both sexes, but especially of women.

The question naturally arises, Is gonorrhœa curable and, if so, when may we pronounce a gonorrhœa cured? Excellent observers, like Behrend and his followers, hold that gonorrhœa, especially in the female, is incurable, and some gynæcologists coincide in this pessimistic view. No doubt there is ample ground for such an opinion. Those who have had occasion to view the specimens gained by operative interference on the female pelvic organs, will bear witness to the ravages wrought on the uterus and its adnexa by the ascending gonorrhœal infection. In the male, strictures, chronic prostatitis, seminal vesiculitis with its attendant prostato- and spermatorrhœa, sclerosing epididymitis, bladder and ascending kidney affections, are items in the evil record of the persistency of the gonococcus. And yet, in the face of all these overwhelming proofs, I am free to assert that gonorrhœa is a curable disease. I admit that the gonococcus, once having invaded the deeper structures, is hard to eradicate, and that the tissue changes due to its actions are wellnigh irreparable; but are not these dire results due to the rough empiric methods of treatment handed down to us from time immemorial; when astringents were the alpha and omega of local treatment in acute gonorrhœal urethritis, and nauseating balsamics had terminated a cure which, in a few instances only, could be looked upon as permanent?

In those times, when the causative factor of gonorrhœa was conjectured but not yet discovered, the want of such an etiological knowledge had biassed the greatest minds, and hence the treatment necessarily could not be other than empiric. But this has changed since Neisser's discovery of the gonococcus, and the researches made by Steinschneider, Schäffer, Schlangenhausen, Gohn, Wasserman, and others concerning the morphology and biology of that microbe. These researches culminate in the following facts: The gonococcus is the only causative factor of gonorrhœa. It traverses cylindrical epithelium with predilection, but under favorable circumstances attacks pavement epithelium also, especially by way of fissured interstices, and may settle in the deeper structures of the mucosa and adjacent connective tissue. This microbe and its toxins induce an inflammatory action on the blood-vessels, causing them to become permeable to the white blood corpuscles and to the transudation of pus serum. The gonococcus and its toxins are pyogenic, and both may cause metastasis in almost any organ of the body, by way of the blood and lymph channels.

But these untoward effects of the gonococcus may in

a measure be avoided, when Neisser's teaching and the treatment pointed out by him are better understood and practised. It is his etiological treatment of acute gonorrhœa with the soluble silver salts which, up to the present time, cannot be superseded by anything else. Their penetrating power to destroy the microbe, even in the deeper strata of the mucous membrane, is unequalled. When these facts shall have become better known to the profession, auto-reinfection by gonococci permitted to become latent in the deeper structures will become a rarer event, and the prognosis of gonorrhœal infection in both sexes will be a more hopeful one.

Regarding the marriage of a patient who has had gonorrhœa, the physician will have a highly responsible question to decide. I here emphatically take the stand against Kromayer's contention that the physician shall decline the responsibility of deciding. Patients yet infectious would in that case marry in larger numbers than now, without asking their physician whether they were justified to do so. Let us utilize the only exact method given us by Neisser, and this is to search for gonococci.

We start with a given case of chronic gonorrhœa. The patient wants to know whether he is yet capable of infecting, and makes his matrimonial venture dependent upon our finding. We have repeatedly examined the threads in his urine, and have found no gonococci under the microscope. On the strength of this examination shall we pronounce this man cured? Certainly not. We will bear in mind that there may be gonococci in the subepithelial and connective structures, in the glands of Littre, in the lacunæ of Morgagni, in the prostate, and in the seminal vesicles. What means do we possess to entice these parasites to the surface? We will apply to the urethra a provocative injection of either a two-per-cent. solution of nitrate of silver or an irrigation of a warm solution of bichloride of mercury, 1 in 10,000—preferably the former one. A reactive irritation of the mucous membrane will follow, and a discharge, more or less copious and of short duration, will be established. We will find leucocytes, epithelia in various transition forms, mucus, and gonococci if such were present in the deeper structures. But right here the gravity of the question is apparent. The presence of gonococci is proof positive, and needs no further confirmation. But if repeated and thorough examinations have failed to show the presence of gonococci, are we just as positively enabled to draw our conclusions from this negative result? Certainly not. There are several possibilities: (1) That there are really no more gonococci present. (2) That there may be gonococci present, but we have failed to demonstrate them, either because of faulty technique, or because the provoked discharge did not dislodge them. (3) That the discharge contains pus corpuscles in abundance, but no gonococci.

To determine the first two points and make sure that there are no more gonococci present, or if supposedly present, we have somehow failed to demonstrate them by the microscope alone, we must have recourse to another process of examination; namely, to cultures. The best culture medium for the gonococcus is human chest serum-agar. To inoculate such a tube or plate, and breed the germs in an incubator, will be an easy task for those possessing a knowledge of bacteriology and an outfit. Those not versed in such researches will do well to send the specimen to a laboratory for examination.

The practitioner in this country is getting accustomed to sending the culture tube, inoculated by him with the exudation of his patient's throat, to the bacteriological department of his board of health, in order to obtain a bacteriological diagnosis of diphtheria. I sincerely hope that hypercritical moralists will not obstruct legislation if, by a concerted action of medical societies, the local boards of health should be obliged or permitted to examine gratuitously, or for a small fee, the suspicious secretions or threads. This could be done by collecting the pus or the threads in a small sterilized test tube, and sending it in for examination.

Heiman has shown that, of the contents of such tubes when sown on plates, the gonococcus can be obtained and isolated, when brought to the laboratory hours later. The mode of obtaining the threads in the usual way, by fishing them out of the urine, is a faulty one, and does not permit of a conclusive result. In case of a negative result, even if Gram's decolorization had been used, we will always entertain some misgivings as to whether one or the other of the unexamined threads might not perhaps have contained gonococci. Therefore I deem it indispensable, in order to exclude any fault in the technique, to make use of the centrifuge.

It seems that Heiman was the first to employ the centrifuge in connection with culture media, for the collection of gonorrhœal threads. The threads thrown down by the centrifuge are afterward inoculated on the culture medium. Thus we are sure that all available threads have been planted, and if gonococci are present, they will certainly show up in colonies. These are now subjected to a microscopical examination. It is essentially necessary that the decolorization by Gram's method be used, as this alone furnishes a reliable criterion in determining whether the culture is or is not that of a gonococcus. The examination of cover-glass preparations, first with the methylene-blue staining, and then after Gram's method, gives for all practical purposes very satisfactory results. But in deciding the advisability of marriage we must avail ourselves, not only of a thorough clinical and microscopical, but also, and foremost, of a bacteriological examination with the use of Gram's method.

When using the urine, that is, the filaments or threads suspended therein, for cover-glass examination only, we will direct the urine to be voided in two portions. It is best to centrifuge it, even for this purpose. In a gross way, the "first portion will contain the threads of the anterior urethra, the second the secretion of the posterior urethra, and probably of the prostate if that is pressed upon while the patient is urinating. It has been shown elsewhere how to proceed when we desire to determine the locality whence the threads and the expressed material are coming. For simple cover-glass examination we will place the thread on a slide, spread it out with a sterilized platina loop, dry it, draw it through the flame, stain it with methylene blue, and examine it under oil immersion. As a control test we will employ Gram's method of decolorization.

If the result of this examination is questionable, we will then at once resort to a bacteriological investigation. For safety's sake we advise the planting of cultures even then, when microscopical examinations have repeatedly yielded a negative result. Cultures will then indicate with an absolute certainty the presence or absence of the gonococcus.

As regards the third possibility, when the secretion contains mostly pus cells as its morphological constituent, we have to deal with a blennorrhagic process, either of a mixed type or a secondary infection. In such a case the gonococci have vanished for good. Either the soil has been made inimical to their growth by other cocci not yet determined, or the gonococcus may have undergone disintegration through hyperplastic connective-tissue changes (strictures), caused by its protracted presence there. We regard such a case as in a sense infectious, and pronounce it as such to the candidate for marriage until his bacillary or catarrhal urethritis is cured.

As the matter stands at present, there are two views current as regard chronic gonorrhœa and permission to marry. That of those who advocate the decision of the question on a purely clinical basis, and that of those who hold the opinion that only microscopical and bacteriological examination should be decisive. It is the old controversy between Behrend, who adheres to the old astringent treatment of gonorrhœa, and Neisser, the founder of the microbic origin and etiological treatment of gonorrhœa with the silver salts. Behrend and his followers, Broeze, Schiller, Kromayer, and others, maintain that "the demonstration of the gonococcus has a positive value only in those cases in which other clinical methods make its use superfluous, while in other cases the demonstration is so unreliable as to be valueless." In the face of the indubitably exhaustive microscopical and bacteriological researches of Neisser, Ernest Frank, Janet, Finger, and a host of other investigators, the contention of the former investigators is an untenable one. The antiseptic treatment of gonorrhœa, in connection with examination for gonococci, is without doubt the only rational method at present. It rests on exact scientific facts, and cannot be replaced by a solely clinical aspect of the matter.

Kromayer maintains in a recent publication that the physician has no right to give permission to marry, even after repeated examinations have shown that no gonococci are present. While we are perfectly aware that these may be lurking somewhere, in spite of all our endeavors, yet there must be a line drawn somewhere, or else about ninety per cent. of the male population will be condemned to celibacy. Nothing short of mathematical accuracy to demonstrate the non-infectiousness of the individual will satisfy the opponents. But how few, if any, are the instances in our science and therapy in which absolute assurance is possible or required? After the surgeon removes a cancerous neoplasm, can he be blamed when, after all, general carcinomatosis develops? It is agreed that syphilitics may marry after they have undergone systematic treatment, when four or five years have elapsed since the onset of the infection, and at least one year after the last specific symptoms have existed. We know that they marry with reasonable security, and we do know that healthy offspring is begotten. Why then shall gonorrhœa alone be on the proscription list? Surely the syphilitic taint is not less destructive than the gonorrhœal infection. Of course it would be an ideal condition were we enabled to presage with absolute certainty the time when neither of them would be again capable of infecting.

But only the relative is our lot, the absolute is denied to us! To resume our topic, I take the stand that we will give permission to marry to those having had gonorrhœa when, after repeated and careful microscopical examination of slide specimens, and an exhaustive bacteriological and microscopical investigation of the threads and of the secretions of the prostate and seminal vesicles, done under the strictest rules and with the aid of Gram's method, the presence of gonococci cannot be demonstrated.

77 East Ninety-first Street.

Importance of Immediate Examination of the Urine in the Determination of its Specific Gravity.—Umberto Baccarani urges that urine should be examined as soon as it is collected, inasmuch as the density changes later. The variations frequently do not obey the laws of physics, and we are often obliged to add to or to deduct from the figure obtained by the ureometer one degree for every three above or below + 15° C. Two specimens of urine may possess the same density at the moment of emission and be quite different after cooling.—*Rivista Critica di Clinica Medica*, February 16, 1901.

EXCISION OF ANEURISM, WITH A REPORT OF TWO CASES OF FEMORAL ANEURISM SO TREATED.

By GEORGE RYERSON FOWLER, M.D.,

Brooklyn, N. Y.,

Surgeon to the Methodist-Episcopal Hospital; Surgeon-in-Chief to the Brooklyn Hospital; Senior Surgeon to the German Hospital.

There can be no question as to the desirability of complete excision, when practicable, of an aneurism, in order to obtain a complete cure. The advantages of such a procedure are such as to warrant the surgeon in prolonging the operation sufficiently to carry out the radical procedure, since the time occupied is not longer than that required for many other radical procedures generally conceded to be not only justifiable but advisable.

By means of this operation the vessel is ligated at its ends instead of in its continuity, and, by the process of ablation of the sac and the adjoining portion of the vessel, provision is made against the two most active factors concerned in the relapse; namely, the existence of the portion of the diseased or injured vessel and the presence of one or more branches concerned in the recurrent circulation. One of the old-time dangers following ligation for aneurism, namely, inflammatory suppuration of the sac and its consequent rupture with hemorrhage from collateral branches, following displacement of occlusive coagula at the points where these communicate with the sac, is rendered impossible by this operation.

While in the second case herewith reported the necessity for ligation of the corresponding vein was carefully avoided, even injury to, and occlusion of, this in connection with ligation and excision of the artery is not attended with great risk of gangrene, as is shown by the first case.

All things considered, it is probable that excision or ablation of aneurism will be the operation of choice in cases in which the diseased condition of the vessel is fairly circumscribed, and advanced inflammatory or other complications, rendering the operation extraordinarily difficult, are absent. In aneurism of the extremities it will be found applicable in the majority of cases, and aneurism involving communication with the corresponding vein constitutes a positive indication for performance of the operation (Case I.).

Experience in the method is still wanting, and it is for the purpose of adding to the literature of the subject that the following two cases are presented:

Case I.—F. A. S——, aged thirty-three years, was admitted to my service in the Brooklyn Hospital with the following history: Twenty-two months previously he received a stab wound in the middle of Scarpa's space. A police officer, trained in first aid to the injured, promptly arrested the profuse hemorrhage with an improvised Spanish-windlass tourniquet of rope, and the patient was removed to an adjoining hospital. When the tourniquet was removed, it was found that the bleeding did not recur. The injury was, therefore, treated as a superficial wound. Suppuration took place, however, three weeks being occupied in the healing. In the mean while the thigh became swollen, and throbbing became marked in the affected part. Upon the healing of the wound, the patient returned to work, but was compelled to give up his employment at the end of two weeks on account of the condition of the limb. At this time, treatment by direct pressure over the pulsating portion of the tumor was instituted, combined with the internal administration of iodide of potassium. Under this treatment the tumor slowly decreased in size, and the patient managed to get about by wearing an elastic bandage.

Upon admission it was found that a "purring" sensation was communicated upon palpation. By the use

of the phonendoscope a continuous gurgling, rushing sound of fluid, intensified at each ventricular systole, was heard all over the right thigh. The point of greatest intensity of this sound was located just above and to the outer side of the commencement of Hunter's canal.

A diagnosis of traumatic arterio-venous aneurism of the femoral vessels was made, and operation advised.

On the following day the aneurism was exposed and the femoral artery ligated immediately above and below the point of communication.

Rapid healing followed the operation, and upon the patient's discharge, twenty-nine days following the operation, no evidence of aneurismal throb in the limb could be detected by the most careful phonendoscopic examination.

The patient was readmitted to the hospital on February 6, 1898, about fifteen months after the operation, at which time he gave the following history:

For several months following the operation the limb remained normal, and he continued his work as a fountain-pen maker. More recently pain and swelling and the "purring" sensation, of which the patient was sensible, returned. Examination showed practically the same conditions present as existed prior to the first operation.

On February 7th, the operation of excision of the aneurism was performed, as follows: An incision was made over the course of the femoral artery, from the base of Scarpa's triangle to the lower end of Hunter's canal. The sartorius muscle was laid bare and retracted to one side. The aneurismal sac, in both its arterial and venous portions, was found to be fully restored. A muscular branch given off from the inner side of the femoral artery between the ligatures, and which evidently had formed a collateral circulation by means of branches from the profunda, fed the sac. The artery was obliterated above and below the sac.

The arterial branch which fed the sac was identified and ligated first. The femoral vein was then ligated above and below the sac, and excised, together with the latter and the remains of the femoral artery. The latter was secured by two additional ligatures, as a precautionary measure before excision.

The patient made a good recovery, and up to the present time (three years after the last operation) has experienced no return of his trouble.

Case II.—L. B——, aged fifty-nine years, male, was seen by me in consultation with Dr. Franklin Bennett and admitted to the Brooklyn Hospital on January 8, 1901. He gave the following history: Family and personal history, as bearing upon the etiology of aneurism, negative, save that two years previously he was struck a severe blow in the middle of Scarpa's space, upon the right side, with the projecting handle of a hand truck. Several weeks elapsed before the lameness from the blow had disappeared. From that time to the occurrence of the present illness nothing to attract attention to the injured part was noticed.

About two weeks prior to the time of my visit, a swelling, accompanied by local pain and tenderness at the site of the old injury, manifested itself. This bore a close resemblance in its clinical aspects to an ordinary inflammatory condition. Palpation, however, revealed a pulsation which was altogether too pronounced and diffused laterally to be accounted for upon the theory of transmission of the arterial impulse through an inflammatory swelling.

Femoral aneurism was diagnosed, and the patient was sent to the Brooklyn Hospital, where the operation of excision was carried out as follows:

With the patient under ether, an incision was made over the most prominent portion of the swelling, and the sac of the aneurism exposed. The structures overlying and surrounding the sac were matted together and adherent to the latter. The vessel was traced in an upward and downward direction until healthier portions of the artery were found, when a ligature, consisting of three strands of catgut, was placed encircling the artery, just below the profunda femuris, and tied in a Ballana and Edmund's "stay knot."[1] A second ligature was placed an inch below the first and the vessel divided between. A provisional ligature was now passed beneath the vessel in Hunter's canal as a precautionary measure, the ends being grasped with a clamp, ready for tying in an emergency.

The excision of the aneurism and adjoining portions of the vessel was now proceeded with. Commencing at the upper portion, the artery was carefully lifted up and separated from its surroundings. Owing to changes in the vessel in the neighborhood of the sac, as well as in the latter, this portion of the operation was carried out with the greatest care, lest the vessel be torn and an undue amount of blood lost, since it was evident by the decided pulsation in the artery that the disturbing influences of the aneurism had led to the establishment of a very pronounced collateral circulation, in advance of the operation.

At the site of the most prominent portion of the sac posteriorly, the latter was found to be intimately adherent to the femoral vein. This portion was, therefore, left undisturbed, and the excision of the remainder accomplished. Each branch of the femoral below the profunda, as encountered, was identified and divided between two ligatures. This was continued until Hunter's canal was reached, when the previously applied provisional ligature was tied. The portion of the sac adherent to the femoral vein was then carefully separated, the sac itself being torn in the process; the vein, however, was uninjured.

The adductor longus, adductor magnus, and sartorius muscles, which had been forcibly retracted throughout the operation, in order to gain free access to the operating-field, were now replaced, and the long skin incision was closed by means of an intracuticular suture. Sterile gauze dressings were applied and the limb was enveloped in cotton and bandaged.

The patient suffered very little shock from the operation. The limb remained perfectly normal, and everything went on promisingly until the end of the second day, when pulmonary congestion, followed by a rapid pulmonary œdema, terminated the patient's life.

CONSERVATISM IN THE DIAGNOSIS AND TREATMENT OF PROSTATIC HYPERTROPHY.

By JAMES R. HAYDEN, M.D.,

NEW YORK.

Although exhaustively discussed and frequently written upon, the subject of prostatic hypertrophy and its treatment is still of the greatest interest and importance to all surgeons, not only on account of the frequency and serious nature of the affection, but also because of the selection of the safest and most suitable mode of treatment for each individual case, the proper solution of which latter problem is of such vital importance to the patient, and often most difficult for the surgeon; there being a dangerous tendency at the present time to subject all cases to operative interference before palliative local treatment is tried, as a result of which a more thorough and exact examination can subsequently be made, thus adding vastly to the surgeon's knowledge of the local conditions, and therefore placing him in a better position to determine accurately what operation if any is best suited to his patient.

[1] "Ligation in Continuity," London, 1891, p. 394.

After carefully reading the records and histories of many of the reported cases of operation for prostatic hypertrophy, but especially those by the Bottini method, one is very forcibly impressed by some if not all of the following facts:

The large number of patients now being operated upon, whose symptoms, judging from their recorded histories, hardly warrant such heroic methods, especially in these days of improved technique as to catheterization and urethro-vesical irrigation, to say nothing of internal medication, improved soft-rubber and woven catheters, and the employment of local treatment to the prostate by way of the rectal route.

Also that, as a general rule, these patients seem to be advised to undergo immediate operation before having had the benefit of an intelligent and sufficiently long palliative or preparatory treatment.

Again, that many of the symptoms that these patients present, and for which operation is advised, are due as much to posterior urethritis and prostatitis, as to a true hypertrophied condition, and that the seemingly brilliant results, so prematurely reported following operation, could have been frequently obtained by rest and proper non-operative interference. It is, I think, a well-established fact, and one that is conceded by most authorities, that in the vast majority of cases of prostatic hypertrophy there is also a considerable degree of posterior urethritis, compressor spasm, urethrocystitis, and true prostatitis, with temporary swelling of the gland, which when removed by palliative treatment, as it usually can be, gives the patient great relief as to frequency in urination, size and freedom of stream, residual urine, pain, clarity of urine, and actual decrease in the bulk of the gland, which latter condition can be appreciated both by rectal touch and the easier passage of urine and urethral instruments.

Palliative treatment also has the great advantage of lessening the congested condition of the prostatic vessels, and also those about the bladder base and neck, so that in the event of subsequent operation the danger of severe hemorrhage will be materially lessened.

Although not intending to claim too much, nor being oversanguine in regard to non-operative treatment, and thoroughly appreciating as I do the great value of operative interference in many of these cases, yet I am thoroughly convinced that, in a goodly number, non-operative methods will give much relief if nothing more, and put the prostate, urethra, and bladder in a more suitable condition for any operation that may later be deemed advisable by the surgeon; in other words, that a diagnosis of prostatic hypertrophy having been made, the patient should have the advantage of such palliative treatment as will accomplish the above results before being hurried into an operation which, even in skilful hands, is a more or less dangerous one. Cases of chronic congestion of the prostate, with perhaps some hypertrophy, are, I am convinced, not infrequently subjected to an immediate and sometimes needless operation, whose mortality is still quite high, and which perhaps might be somewhat lowered if the inflammatory element were more thoroughly appreciated and treated, thus leading to a more intelligent selection of cases for operative interference. If the surgeon inquires carefully into the previous life of his prostatic patient, he will find in a goodly number, either a history of posterior urethritis or gonorrhœa, with or without stricture formation, or perhaps a urethrocystitis following forcible or uncleanly instrumentation, or catheterization for retention, or some irregularity or abnormality in his sexual life or relations, any of which conditions if unrecognized, or improperly or insufficiently treated, are in themselves sufficient to cause or keep up more or less irritation and congestion in the deep urethra and prostate gland, which element of irritation and congestion finally ends in chronic inflammation which is likely in time to lead to enlargement of the glandular and other prostatic elements, and therefore must not be forgotten in the diagnosis and the treatment of prostatic hypertrophy.

The palliative or preparatory treatment above alluded to consists in keeping the urine of as normally acid reaction as possible, both by internal medication and a properly selected diet; boric acid or urotropin in full doses is very efficient when the urine is either neutral or alkaline. If, on the other hand, it is overacid and irritating, we should administer alkalies, either alone or combined with hyoscyamus, kava kava, triticum repens, or uva ursi.

Rectal irrigations of hot salt solution at from 110° to 120° F., once or even twice daily, cause a marked improvement in the painful and inflammatory symptoms referable to the prostate, bladder, and compressor muscle, and also in the size and consistence of the gland. The hot sitz bath and hot perineal applications are also sometimes serviceable.

The amount and character of the residual urine is carefully noted, and if indicated it is drawn at regular intervals, with soft and sterile catheters, and the bladder and urethra are medicated by means of irrigations or instillations, according to the clarity of the urine and the amount and character of the residuum.

Prostatic massage is, as a rule, not indicated in these cases, as it increases rather than subdues inflammation; but if employed, it should be performed very gently, at long intervals and with the finger; the use of specially constructed rigid instruments for this purpose is to be emphatically condemned as rough and inaccurate.

Variously medicated rectal suppositories sometimes seem to act favorably, and may therefore be tried. Rest in the recumbent position benefits some, while other patients are more comfortable when up and about.

Hemorrhoids should always receive prompt and efficient treatment, as they frequently complicate and aggravate this class of case. If stricture is present it should be slowly, gently, and moderately dilated, or if that is impossible and it interferes with treatment and hinders convalescence it must be incised in a very conservative manner. If the case is complicated by vesical stone, the latter should be removed, either by litholapaxy or a cutting operation, according to the indications.

As a result of the above treatment, carefully carried out in all of its details, the prostate becomes much smaller and softer, the amount of residual urine is diminished, the urine becomes clearer and assumes a more normal reaction, and the pain, frequency, and straining gradually subside.

Now is the time to settle the all-important question in regard to the advisability of operative interference, or of relying on the catheter and suitable local and internal treatment.

In regard to the operative treatment of prostatic hypertrophy, I think it may be safely stated at the present time that the most satisfactory method is the partial or complete removal of the gland, either by the suprapubic or perineal route, or by a combination of both of these methods. The Bottini operation may perhaps be of some service in certain carefully selected cases, but it does not give as immediate and free vesical drainage as does prostatectomy, which is a strong argument against its general adoption, as prompt and unobstructed drainage of the bladder is a most important factor in the treatment of these cases.

Castration, vasectomy, and ligation of the internal iliac arteries are not to be recommended.

SUBPHRENIC ABSCESS AS A COMPLICATION OF APPENDICITIS.

By J. McF. GASTON, Jr., A.M., M.D.,

ATLANTA, GA.

The literature of this subject is necessarily limited. The standard text-books on surgery do not recognize appendicitis as one of the causes of subphrenic abscess. The most frequent causes mentioned are traumatic or ulcer of the stomach or duodenum.

The large experience of Wyeth [1] has brought under his observation only three cases of subphrenic abscess, and one of them was in association with the lesion of the kidney.

Ashhurst [2] has given it as his opinion that a large number of cases of appendicitis may be treated medically by opium and belladonna, and that even recurrent cases do not necessarily call for the knife. In this line I repeat my own position before the Medical Association of Georgia, that each case should be considered "carefully and, I might say, prayerfully."

Leyden is one of the few writers to classify perforation of the vermiform appendix as a frequent complication of subphrenic abscess. He also mentions duodenal ulcer and empyema. His illustration shows the positions of the liver and of tympanites with great precision. The liver is pressed down and the pus presses the diaphragm up.

The subject of subphrenic abscesses caused by perforation of the vermiform appendix, and complicated in a great many ways with diseases of the abdominal cavity, has been ably treated by Osler and Mason, with discussions by Welch, Fitz, and others.[3]

Leyden and Ranvers[4] report cases of subphrenic abscess as occurring both in private and hospital practice. Leyden has been quoted by Baldwin,[5] in his article on "Subphrenic Abscess Following Appendicitis," as stating that the liver is somewhat depressed, and there is often pain in the shoulder blade, with hiccough, and amphoric breathing below but not above the eighth or ninth ribs.

W. E. F——, aged thirty-two years, was seen by me for the first time on June 3, 1900. His family physician, Dr. J. W. Carmichael, had seen him the night before, and asked me to examine him with reference to pain in the region of the appendix. Dr. W. Monroe Smith had seen him when he was first brought home. His condition had led him to give him a hypodermic of morphine gr. $\frac{1}{4}$, and atropine gr. $\frac{1}{150}$.

The patient at 7 A.M. was found to have a temperature of 100.2° F.; respiration, 26; and pulse, 100. His countenance and general appearance gave evidence of a strong, robust man, prostrated by some serious complaint. The following prescription was given to be filled and used: Ung. belladonnæ, ℥ i.; pulv. camphoræ, ʒ i. Sig. Apply to the abdomen, and cover with oiled silk.

Dr. Carmichael had administered a large dose of calomel, so that this was now followed by a tablespoonful of Epsom salts.

The patient's condition betokened a fulminating appendicitis, and so the family physician remained to watch carefully and record his temperature, pulse, and respiration every half-hour until he could be seen again.

In the mean time all preparations were made for an operation, and the family was advised of the necessity for surgical intervention. At 11 A.M. of the same day, Drs. J. McFadden Gaston, Sr., J. W. Carmichael, and W. Monroe Smith met me to proceed with the preparations for the operation. The patient was given morphine sulphate gr. $\frac{1}{4}$, and atropine sulphate gr. $\frac{1}{150}$ hypodermically. His pulse had shown a marked acceleration, and the pain and suffering became unbearable. Two tablespoonfuls of castor oil and one teaspoonful of spirits of turpentine were administered, but no action of the bowels took place before the operation. A. C. E. mixture was administered by Dr. Carmichael. The parts in the region of the intended incision were shaved and thoroughly cleansed with soap and water, solution of carbolic acid, and ether.

An incision one and one-half inches in length was made over the tumor noticed in the right iliac region, near the border of the rectus muscle. This was increased to nearly three inches before the operation was completed. The fibres of the transversalis muscle and the rectus were divided with tearing motion of the fingers, and finally the aponeurosis was reached, and an aperture made for the insertion of a director which was used to guide the scissors in cutting. In the same way the peritoneum was divided.

A small amount of dark fluid told of disintegration of tissue in the region of the appendix. A large piece of omentum was excised after being ligated with catgut. The appendix was ligated with silk and cut with scissors. The appendix was gangrenous, and contained one enterolith. A portion of tissue near the appendix being ulcerated was excised. The stump was treated with carbolic acid and allowed to drop back with no elaborate toilet.

The whole of the area of the peritoneum that could be seen was wiped with absorbent cotton, covered with sterilized gauze, previously dipped in hydrogen dioxide. Irrigation with decinormal salt solution and hot water was used. The peritoneum was sutured with interrupted catgut sutures. The fascia, muscles, and aponeurosis were closed separately. Finally the skin was sutured with interrupted silk ligature except at the lower angle, which was left open for gauze drainage. The patient stood the anæsthetic well, and was placed in bed, and given a hypodermic injection of strychnine nitrate gr. $\frac{1}{30}$. He slept until 6 P.M., and when seen at 7:35 P.M. was not very restless. The temperature was 101°; pulse, 95; respiration, 21.

I remained with him during the night, and he was very much nauseated from the anæsthetic. The same ointment mentioned was continued on the chest and left side: the dressing on the right side was not disturbed, except for the purpose of loosening the strong bandage that became too tight as the gases of the intestines distended them. He asked for morphine and water, but neither was given him; neither was permitted. At 9:30 P.M. an enema of sulphate of magnesium ℥ vi. was given. Another hypodermic of strychnine nitrate gr. $\frac{1}{30}$ was given at 11:30 P.M., when his temperature was 99.8°, pulse 105, and respiration broken by retching. A quantity of bile was vomited. The respiration was hurried, and was not recorded at this time, but at 10 P.M. his pulse was 95 and temperature 100.2°.

Next morning at five the temperature was 100, pulse (better tone) not recorded as distinctly counted. At 8:30 A.M., temperature, 99.5°; pulse and respiration still indistinct. At night, at 10 o'clock, the temperature was 100.2°, and at 11:25 101°, but the pulse was 80, and the respiration 35. It had been found advisable to keep up every hour a tablespoonful of the following: Lime water, ℥ iii.; peppermint water, ℥ i.; camphor water, ℥ ii. Diffuse peritonitis seemed to have existed with tympanites and pain. The tongue was red and raw, of a typhoid nature, while the respiration was irregular, spasmodic, and accelerated.

The pulse, however, was the chief danger signal,

[5] Virginia Medical Semi-Monthly; Medical News, July 14, 1900; Cleveland Medical Journal, August, 1900; reviewed by Journal of American Medical Association, September 18, 1900.

and in this I coincide with Dr. George F. Shrady[1] lies the chief index of the disease; or in his words, "It is wise to refuse to operate during the attack when the pulse rate lessens, when the pain diminishes, and when the temperature falls." The form of treatment instituted was that usually pursued in cases of a septic tendency. Frequent dressings were used and free drainage was secured. When the temperature and the different symptoms suggested a lack of biliary secretion, small doses of calomel were used. These produced full discharges, and great relief therefrom.

Drainage of a small piece of sterilized gauze, about one inch in width, was obtained from the stump. The use of dioxide of hydrogen was continued for four weeks. The sublimate gauze was substituted for sterilized gauze on the third day, when the wound was found to show signs of healing externally. But owing to the fetid discharge noticed on drainage of gauze, an opening was kept up. The best means thoroughly to disinfect the internal parts, and to pick out dark and necrosed tissue, were used at each dressing twice daily. The iodoform gauze was packed into the wound on the tenth day, after the stump was healing, as shown by the discharge of ligatures and the sloughed mass in which it was. The whole of the wound was filled with masses of gangrenous tissue. Upon remembering the fluctuation detected in the subdiaphragmatic region, it was thought necessary to reopen the wound and to favor drainage down through the original wound; this was the more urgent by the symptoms of pus. About this time Dr. Baldwin's paper appeared in the *Virginia Medical Semi-Monthly*. A complication of subdiaphragmatic abscess was evident. The pyogenic membrane and pus finally escaped at a dressing.

Milk was allowed for nourishment, and when no mercurial contraindicated its use, fresh buttermilk was allowed and greatly relished.

Frequently great pain was experienced in the wound, but no morphine was allowed to be used, soothing local applications being sufficient.

A combination of bromides with other sedatives served a good purpose internally. As tonics, elixir of iron, quinine, and strychnine, tr. cinchona co., and strychnine nitrate tablets were administered as indicated.

Soon after the operation great difficulty was experienced in securing movements of the bowels. For this purpose enemata of sulphate of magnesium were used. Finally a large colon tube was inserted by Dr. Carmichael, and a complete evacuation was secured.

The diet was confined to broths and soups for some time.

A record of his condition, each day, was kept, and may be judged by his temperature, respiration, and pulse in the following table below.

Date.	Hour.	Temp. (deg. F.)	Respiration.	Pulse.	Remarks.
1900.					
June 1...	7:30 A.M.	.....	..	..	Onset. Pain in McBurney's point.
June 2...	9:30 P.M	102.0	30	..	Hypodermic of morphine and atropine.
June 3...	. .....	100.6	30	90	Pain; tenderness; tympanites, fluctuation under costal arch.
June 5...	9 A.M ...	100	20	90	When asleep, pulse 70.
	6:45 P.M	102

Some remarks may be appropriate in reference to subphrenic abscess following appendicitis, for we find that rarely does this complication occur. Baldwin's cases make the forty-fourth and forty-fifth cases. He has studied the statistics presented in the monographs of Leyden, Maydl, and Sachs, with the addition of some cases reported in this country. Many of the cases were not diagnosticated until after the death of the patients revealed the condition. Pathological examination has shown that these cases may be extraperitoneal or intraperitoneal.

Baldwin's first case was one in which the appendix was found behind the cæcum, causing him to believe that the infection extended upward behind the peritoneum, and that the entire abscess was extraperitoneal. In this case the first operation was done June 6. 1899, and not till July 20, 1899, did the presence of a chronic abscess, pointing on the right side, become evident, and on the following day was evacuated by an incision immediately under the twelfth rib, an enormous amount of pus coming from a large cavity lined with ragged edges and extending up toward the diaphragm above the liver. After the rough drainage the cavity closed in about six weeks.

The second case was in a young lady, sixteen years

[1] The American Year-Book of Medicine and Surgery for 1898, p. 310, quoting Treatment of March 25, 1897.

old. She was operated on the first time July 26, 1899, and then again on August 28, 1899. The last time was for the subphrenic abscess which had appeared below the twelfth rib. The liver was found normal, but with a mass of exudate back of the suspensory ligament with evident adhesions at this point. Baldwin describes the pus cavity found as about the size of a small orange, with a somewhat ragged interior, which was washed out, with a counter-opening for drainage. In this case the abscess cavity was packed with gauze, and closed in two weeks.

In my case the symptoms from the start were evidently due to a subphrenic abscess from fluctuation below the twelfth rib and the rapid respiration. A channel, so to speak, was opened up by the cutting away of a large obstruction of adherent omentum during the operation for appendicitis.

The pyogenic membrane must have been very strong, as no pus was evacuated from this region when it was explored by my fingers. No septic contamination resulted on account of this thorough isolation of the subphrenic abscess from the appendical wound. The extension of the inflammation may have been extraperitoneal as in Baldwin's case. The direction of the discharge was from the diaphragm as shown by coughing and deep respiration bringing on quite a sudden outflow of pus. It could not have been an appendical abscess alone, for no connection with this part of the wound seemed to exist. In Baldwin's cases there was a longer interval between the subsidence of symptoms in the appendical region before pus was found above. Yet the case I report was so much more protracted that no other explanation could be given. Then the recovery was very prompt and permanent. The outcome was peculiarly fortunate, not requiring another operation.

One may seek to find, in his previous history, some cause for this subphrenic abscess; and it was ascertained that he had received a blow in his work on the railroad several months before. The pain and inflammation at this time remained in abeyance until after the time when the appendix was involved. The subdiaphragmatic abscess was certainly the most dangerous feature of his case, and could not have been cured by the entire closure of the wound as advocated by Joseph Price and others dealing with appendical abscesses alone.

SURGICAL TREATMENT OF ABDOMINAL DROPSY FOLLOWING CIRRHOSIS OF THE LIVER.[1]

By JAMES T. JELKS, M.D.,

HOT SPRINGS, ARK.,

PROFESSOR OF GYNÆCOLOGY AND SYPHILOLOGY IN BARNES MEDICAL COLLEGE, ST. LOUIS, MO.

In writing the following article and reporting the case appended, I do so that I may call the attention of the profession to this heretofore incurable condition. I report the case, not that it, as yet, proves anything for the operation, but simply use it as an illustration and text in an effort to popularize the surgical procedures narrated. I sincerely trust that the profession will take up this subject and give these unfortunates an opportunity to get well.

From time immemorial, abdominal dropsy following cirrhosis of the liver has been considered an incurable condition. We have all recognized it as invariably fatal, and, until the last few years, but few if any of all the thousands suffering from it have had the inevitable end postponed by anything which we could do.

A pathfinder has been at work for these hopeless ones. In 1889 Von der Muele performed the operation which I shall describe below, but it was unsuccessful. In 1891 Schelky had a like unfavorable issue to his case, death following from septic peritonitis. In 1892 Lens, of Holland, operated. His patient survived the operation, but was not cured of the dropsy. Morison's first case also resulted fatally, but the second patient not only recovered from the operation, but from the dropsy as well. This operation was performed October 22, 1895.

Since this date, ten cases have been reported, the last one by Dr. Charles H. Frazier, of Philadelphia. This patient was tapped on the thirteenth and thirty-sixth days after the operation. At the end of five months the dropsy had not recurred, and thus was added another to the list of successful cases. For the connected history of this operation and tables of all reported cases I am indebted to Dr. Charles H. Frazier, of Philadelphia, and his article in the *American Journal of the Medical Sciences* for December, 1900. More than a year ago I offered this operation to a patient, but it was declined. I have had no other case until the one presented, the details of which will follow.

Nature attempts to do the thing for which the operation was suggested, viz., to make collateral channels by means of which the portal blood can get back to the heart by other than its normal route. We have all noticed the enlarged veins coursing over the abdomen and the caput Medusæ about the navel. According to Frazier, there are other vessels which have also engaged in this effort to save these patients—the "coronaries anastomose, through the œsophageal plexus, with the azygos veins; the hypogastric with the hemorrhoidal; the veins of the hepatic ligament with those in Glisson's capsule; the veins of the round ligament with the epigastric." All this, however, has not sufficed to carry this portal blood around the obstruction, and hence the surgical procedures, which have been crowned with success.

Operation: This consists of abdominal section, preferably between the umbilicus and ensiform cartilage, evacuation of the accumulation of fluid, and scraping of the parietal peritoneum with a curette or rubbing off of its epithelium by means of a gauze sponge. The superior surface of the liver and the peritoneum covering the diaphragm are also to be rubbed. The omentum for three or four inches around the incision is then to be stitched to the parietal wall. It is also included in the sutures which close the abdominal incision. Thus a broad surface is presented for adhesions, and it is this additional collateral circulation which has saved these patients. Of course these people are not cured at once of their dropsy, but nature must have time to enlarge this additional collateral circulation until it can do the work expected. To this end these patients may be compelled to have the water drawn off several times.

Indications for the operation: I believe every patient suffering from ascites, as a result of cirrhosis of the liver, should be subjected to this operation. Of course a new thing is likely to be abused, and bad diagnoses will be made and patients subjected to section who should not be; still, the operation has a great future before it, and is destined to prolong many lives. As a rule, these patients are past the prime of life and are rapidly going down hill when they are first seen; hence they are not very promising cases for the surgeon's knife and the anæshetic. Because of these facts local anæsthesia is advised by Frazier. Experiments have demonstrated that the passage of the portal blood direct from the portal veins into the vena cava is fatal to dogs because of the auto-intoxication which follows, by reason of the fact that the liver has had no opportunity to purify this blood. Some of the patients saved by the operation have complained of certain nervous symptoms due to auto-intoxication.

TABLE NO. I. (FROM FRAZIER).

No.	Operator.	Sex.	Age.	Conditions Found at Operation.	Result.			Remarks
					Immediate.	Ultimate.	Ascites.	
1.	Drummond and Morison.	Female.	48	Liver enlarged; surface smooth.	Recovery.....	Death 19 months...	Recurrence.	Required frequent tappings.
2.	Drummond and Morison.	Female.	35	.....	Recovery	Recovery[1]	No recurrence.	Perfectly well after lapse of two years.
3.	Morison	Male.	42	Liver cirrhotic; spleen enlarged.	Recovery.....	Recovery	No recurrence.	Suffered from nervous phenomena, result of intestinal intoxication.
4.	Morison	Male.	54	Cirrhotic liver; splenic tumor.	Death 11th day.	.....	.....	Patient died, supposedly from contracted kidneys.
5.	Ewart	.....	....	Liver not cirrhotic..... ...	Recovery.....	Death several months.	Recurrence....	Operation had no effect on ascites.
6.	Schelky.....	.....	....	.....	Death 14th day.	.....	.....	Patient died of delirium tremens.
7.	Lens.	Male.	61	Atrophic liver.....	Recovery.....	Death 6th month...	Recurrence....	Failure of operation attributed to atrophic condition of liver.
8.	Talma.....	Male.	9	Liver enlarged; surface granular; parenchymatous nephritis.	Recovery.....	Recovery.....	No recurrence.	The patient was perfectly well twenty-six months after operation.
9.	Neumann	Male.	45	Splenic tumor.....	Recovery	Recovery	No recurrence.	Patient had no ascites six months after operation.
10	Weir.....	Male.	39	Liver capsule thickened; spleen bound by adhesions.	Death 5th day.	.....	.....	Patient died of purulent peritonitis.
11.	Rolleston and Turner.	Male.	45	Surface of liver granular; splenic tumor.	Recovery.....	Recovery.....	No recurrence.	Patient when seen four months afterward was perfectly well.
12.	Rolleston and Turner.	Male.	52	Liver cirrhotic.....	Recovery.....	Unimproved.....	Recurrence....	Patient four months after the operation was bedridden; ascites and œdema of the legs.
13.	Bossowski.....	Female.	9	Liver cirrhotic.....	Recovery ...	Recovery.....	Recurrence....	Ascites developed less rapidly after operation.
14.	Frazier.....	Male.	45	Liver cirrhotic; omentum short and thickened.	Recovery.....	Recovery.....	Tapped twice..	Three months after operation there is no evidence of reappearance of ascites.
15.	Jelks	Male.	59	Cirrhosis and atrophy.....	Recovery.			

[1] Died from effects of an operation, two years later, for ventral hernia.

Results: From the table quoted above we see that three died within two weeks of the operation—one from contracted kidneys, one from septic peritonitis, and one from delirium tremens, who, while delirious, tore off the dressings and infected the wound. In two of the cases reported, the liver was not cirrhotic.

TABLE NO. II. (FROM FRAZIER).

Died within two weeks	3
Died in nineteenth month without improvement	1
Died in sixth month without improvement	1
Died in sixth (?) month without improvement	1
Living, but unimproved	1
Living and slightly improved	1
Living and free from ascites at periods of 3, 4, 6, 24, 24, and 26 months respectively	6

Excluding those cases of failure for which the operation should not be held accountable, the following remain:

TABLE NO. III. (FROM FRAZIER).

Died within two weeks	0
Living, but unimproved	1
Living and improved	1
Living and free from ascites at periods of 3, 4, 6, 24, 24, and 26 months respectively	6

A comparison between these two tables would be expressed in figures as follows:

Mortality, Table No. I.,	21	per cent.;	Table No. II.,	0	per cent.			
Unimproved	"	"	28	"	"	"	12.5	"
Improved	"	"	8	"	"	"	12.5	"
Recovery	"	"	43	"	"	"	75	"

J. L. B——, aged fifty-nine years, last summer, while visiting the summer resorts of the north, noticed that his abdomen began to enlarge, and by the time he returned home in September it was very greatly distended. When I saw him, I at once proposed cœliotomy, with the object of forming adhesions between the omentum and the parietal peritoneum. To this operation he declined to consent, and I resorted to purgation and diuretics, with only temporary relief. At the request of the family, Dr. W. S. Walker, of our city, was called in consultation, and he independently advised cœliotomy also. Again the patient and family declined it, and the former was tapped, twenty-nine pints of water being drawn off. Purgation and diuretics were continued as before, with only temporary amelioration of his symptoms. Finally, after many consultations and a candid explanation of the inevitable end which stared him in the face, he consented to the operation. On December 20th he was removed to the Ozark Sanatorium and careful preparation made for the operation. The day before the operation he was again tapped, and three gallons of water were drawn off.

Operation: I made an incision four inches long, in the median line, between the umbilicus and the ensiform cartilage, and evacuated several pints more of fluid. Then the peritoneum was vigorously rubbed with a gauze sponge for four inches around the incision. The same surface was curetted with the sharp curette; the surface of the liver was also rubbed, after which the omentum was stitched to this denuded parietal peritoneum for three inches on either side. The incision was closed without drainage, by stitching the omentum into the wound with fine catgut sutures; the fascia was then brought together first, by four silkworm gut sutures, and the interspaces were closed with heavy catgut; lastly the skin was brought together by subcutaneous sutures of fine catgut. I was assisted in the operation by Dr. W. S. Walker, Dr. T. E. Holland, Dr. Randolph Brunson, and Paul Turner Vaughan, of Hot Springs, and Dr. Frank W. Jelks, of St. Louis.

The day after the operation his temperature was 97.5° F., and remained so for three days or more. On the fourth day it rose to 98.6°, and remained so. On the eighth day the dressings were removed, and union throughout was perfect, no redness and no tenderness remaining.

For the first twelve hours I permitted nothing in his stomach. At the end of that time he was allowed one teaspoonful of water every hour for twelve hours, when a teaspoonful of a peptonized preparation was given every two hours. On the following day the preparation was increased in amount. On the third day he was given a raw egg in a little sherry wine every four hours. On the fifth day the soft part of a few raw oysters and bouillon were added to his diet. On the seventh day milk was permitted and all the water he wished.

Sleeplessness in Heart Disease and its Treatment.—C. C. Gibbes states that sleeplessness in advanced heart disease is in a large majority of cases

due to the heart itself; but when the diseased heart is compensated, or only commencing to fail, sleeplessness is most frequently caused by irregularity of some of the other organs of the body, the heart being secondarily affected. Consequently the administration of hypnotics without specially treating the exciting cause is only injuring the patient, by masking nature's outcry for help. Inability to sleep is always a most significant symptom. The causes may be divided into nervous and vascular. The capacity for sleep varies, depending on many conditions. The treatment specially required to prevent the recurrence of sleeplessness in heart disease itself may be summed up as follows: (1) Correct as much as possible any constitutional tendency to sleeplessness. (2) Minimize as much as possible the amount of work required of the heart. (3) Improve the tone of the heart-muscle. (4) Treat complications as they arise. The food should be of a light, nourishing character. Salines or some other aperient and mercury greatly relieve the work of the heart. Means should be taken to prevent any chilling of the body surface. The patient's mode of life should be carefully regulated. The writer then briefly describes the most essential hypnotics.—*The Clinical Journal*, January 16, 1901.

Hernia of the Bladder, with Especial Reference to its Pathogenesis.—R. Alessandri says that this affection arises from several causes. Distention and flaccidity of the bladder walls, with diminished resistance of the abdominal walls, are the most important factors in the production of extraperitoneal cystocele. Accumulations of fat may also favor its formation. Congenital diverticula, asymmetry of the bladder, as well as alterations in form secondary to various pathological conditions of the lower urinary apparatus are also to be taken into account. For the formation of intraperitoneal hernia there must be an unusual and almost exceptional mobility of the bladder, accompanied by marked distention and flaccidity of the abdominal walls.—*Il Policlinico*, January, 1901.

Relation of Eye Strain and Pneumogastric Reflexes to Digestive Disorders.—A. L. Benedict says that if we allow the use of the term "eye strain," not in the usual sense of an effort to correct a visual error, but just as we would speak of cardiac strain, or strain of any other normal part by overexertion, he is prepared to admit that it is a very frequent cause of acute gastric symptoms, such as nausea and vomiting. It is not safe to say that sick headache is always due to eye strain, but it does often result from a depression of pneumogastric function by ocular reflexes. The frequency of sick headache in summer is quite as much due to straining the eyes in brilliant sunshine for a long period as to the danger of fermentation in food on account of the heat. Scorchers' sick headache is a good example of the results of eye strain, caused by the effort to fix the eyes on the road while subject to constant vibration of the bicycle; the streaming past the field of vision of objects in the road, the brilliance of illumination on a sunny day, etc., constitute an overexertion of the extrinsic muscles, the ciliary and the iris, as well as a prolonged and marked stimulation of the rods and cones. Car-sickness is, in some persons, a closely analogous condition and due to the same detailed causes.—*Medicine*, January, 1901.

Pathology of the So-Called Functional Neuroses.—Theodore Klingmann finds from a series of experiments that the action of toxic blood of patients suffering from functional nervous disorders is quite as marked as that of those suffering from acute infectious diseases. It is thereby shown that the disease is not really a product of the structural alterations which may be present, but of a hurtful substance or poison capable of producing these structural changes. When we observe such cases early, we may well say that they are functional neuroses, unless we recognize this condition—a toxæmia due to deficient metabolic power and retarded elimination—the injurious effects of which have been demonstrated in the above experiments. Not only are the higher centres ill nourished, but they are irretrievably damaged, their working-power is annulled, and the whole train of evils follows even to insanity. A considerable number of the individuals suffering from these maladies are from the outstart handicapped; they have inherited a feeble organization, their resistive power is diminished, the functions are perverted most readily, and the entire organism reacts with readiness to these injurious attacks. It is therefore not surprising that an accumulation of a deleterious agent in the nutrient fluid of the body should overstimulate, depress, or destroy the functions of the nervous system when morbid heredity previously exists.—*American Journal of Insanity*, January, 1901.

Studies in Regard to the Decidua in Abortions.—M. Barberio, from the result of experimental studies, concludes that in some cases the abortive products may consist entirely of the decidual sac. The absence of the embryo must be supposed to be due to its death in the early stages of gestation, its degeneration and absorption. The decidua is formed by the transformation of all the elements of the uterine mucosa, with the exception of the lining epithelium. The hæmatopoietic and vaso-formative properties of the decidual cells have not yet been established.—*Giornale della Associazione Napoletana di Medici e Naturalisti*, November-December, 1900.

Origin of Hallucinations.—W. Alfred McCorn says that hallucinations are not new creations; they are composed either of present or of latent memory pictures or ideas, and are accordingly designated concomitant or spontaneous, respectively. They are not due to an external stimulus, but to one within the sense organ itself—one acting on its sensory tract or the sensation cells of the brain cortex. Hallucinations may affect any or several of the senses simultaneously, and influence thought and action according to their contents and the importance ascribed to them by the patient. They may be due to toxic conditions—whether caused by drugs or infectious diseases, disorders of nutrition, the effects of extreme heat or cold—and often accompany the functional neuroses. They are particularly common in paranoia and dementia in their various forms, but occur more rarely in the effective psychoses.—*American Journal of Insanity*, January, 1901.

Treatment of Epilepsy by Richet's Method.—Guido Garbini describes the results of this method, which consists in diminishing the amount of salt ingested by patients while they are taking bromides. The effects of what he calls "hypochloridation," combined with small doses (one gram) of bromide, was to reduce the attacks seventy-three per cent. Without bromides, the reduction amounted to sixty-five per cent. The duration of the attacks was diminished about two-thirds. No unpleasant results follow the treatment, which, however, is better tolerated by men than by women. The effects of the treatment are the same, whether the bromides of sodium, potassium, or ammonium are used. The patients experimented upon were given milk, potatoes, eggs, coffee, beef, sugar, and butter, the amount of salt in which was about 2.19 gm., and the addition of salt was absolutely forbidden. The treatment is of easy application.—*Rivista Mensile di Neuropathologia e Psichiatria*, February 1, 1901.

MEDICAL RECORD:

WM. WOOD & CO., 51 Fifth Avenue

New York, March 23, 1901.

TUBERCULOSIS AMONG THE POOR.

THE terrible ravages of pulmonary tuberculosis among the poor is only too vividly shown in the statistics recently published by the prefect of police of Paris, while it appears that among the rich the mortality is comparatively light. To be sure, that the rich furnish fewer deaths from consumption in a city's statistics can in part be explained by the fact that they have the means to seek better climates and thus die away from home, that they have earlier medical attention and hence an early diagnosis, and that better food and more leisure allow them a chance for recovery; and, on the other hand, that the disease, being of a chronic nature and thus gradually impairing the earning capacity of the individual suffering from it, forces him step by step into poorer and yet poorer quarters until, from a simple lack of funds, he ends his days in the worst and cheapest districts. Notwithstanding all these considerations, the statistics point only too clearly the lesson that good surroundings mean comparative immunity. According to the prefect's report, the average number of deaths per ten thousand inhabitants is, in the poorest quarters, sixty-five; in the quarters occupied by the working class, somewhat less; in the well-to-do quarters, thirty-five, and in the richest districts only twenty. To make the lesson still more obvious, the report shows that only fourteen deaths per ten thousand per annum occurred in the Champs Elysees quarter, while in the Buttes-Chaumont district it reached sixty-nine, nearly five times as large a number.

In Hamburg the statistical evidence, as given by Gebhart, points the same moral; for according to him the death rate among those having less than $500 per annum income is forty per ten thousand, while among those whose income is above that figure the rate is but fifteen per ten thousand.

Can we not learn from these proofs, better than from any theory, that the efforts of our various boards of health should in future be directed toward bettering the hygienic conditions existing in the poorer quarters, rather than in the segregation of the individuals already affected? The enforced limitation of building-space on specified land areas, the control of the height of buildings used as lodging-places, the assured entrance of light and air—the best of all disinfectants—into each and every room, all these would constitute practical, applicable, and effective means of checking this white plague. Would it, in the end, be too expensive if we could save thousands of producing workers who, as Mr. Carnegie has so generously acknowledged, are the real sources of wealth?

The protection of the hygienic surroundings of the poor would without doubt not only check the spread of tuberculosis, but many other diseases would also become less frequent. Such a measure would protect the rich as well as the poor, for the distribution of the infectious material would in turn be lessened throughout the whole city, and a common expense would be for the common good.

SOME OF THE MOTOR MANIFESTATIONS OF FACIAL PARALYSIS.

APART from variations in symptomatology due to differences in the situation of the causative lesion, paralysis of the muscles supplied by the facial nerve is not rarely attended with anomalous manifestations. Thus, there is sometimes impairment of sensibility upon the face or the tongue, or taste may be partially lost, or the movements of the palate may be interfered with. The results of an elaborate study of the disturbances of taste, and the secretion of sweat, saliva, and tears in connection with facial palsy, have recently been reported by Köster (*Deutsches Archiv für klin. Medicin.*, B. xxviii., H. 3 u. 4, p. 343); while Bernhardt (*Berliner klin. Wochenschrift*, 1900, Nos. 46 and 47) directs attention to some of the anomalous motor disturbances. The latter had previously (*Berliner klin. Woch.*, 1899, No. 31), in discussing the question of so-called congenital facial palsy, expressed the opinion that such a condition undoubtedly occurs—or, perhaps, rather a defect in the development of the facial muscles. This may be unilateral or bilateral, and it may involve completely or partially the ocular muscles and less commonly those supplied by other cerebral nerves, as the muscles of the lips and the chin.

It has been noted by a number of observers that at times stimulation of muscles upon one side of the face is followed by contraction not alone of these muscles, but also of the corresponding muscles upon the opposite side. An explanation of this fact is to be found in some cases in the anatomical condition, some of the muscular fibres passing from one to the other side of the face. In a girl presenting symptoms believed to be due to inflammation of the pons occurring in childhood, and attended with unilateral facial paralysis, Oppenheim (*Berliner klin. Woch.*, 1899, No. 19) had found that electrical stimulation of the facial nerve on the unaffected side induced contractions of some of the facial muscles on the opposite side close to the middle line, and this with current strengths insufficient to induce contractions on the unaffected side or directly upon the affected side; and he attributes the phenomenon to innervation of the muscles on the affected side by possibly newly formed nerve fibres from the unaffected side. Observations apparently in confirmation of this view were subsequently reported by Mohr (*Berliner klin. Woch.*, 1900, No. 30, p. 851).

Weir Mitchell (Transactions of the American Neurological Association, 1877, vol. ii.) had many years previously observed that electrical stimulation of the muscles of the chin or the lips near the middle line caused contraction of the muscles on the opposite side, both in health and in disease. This was at first thought to be due to reflex action, but it was later attributed to currents induced between and beyond the two poles, and this explanation appeared to be supported by the results of certain experimental observations. Hoffmann (*Deutsche Zeitschrift für Nervenheilkunde*, B. ix., p. 266) has reported a case possibly of encephalitis, with unilateral facial palsy, in which electrical stimulation of the unaffected side induced more marked and more extensive contraction upon the paralyzed side; and he concluded that the manifestation was reflex.

Benedikt ("Electrotherapie," 1868, p. 65; "Nervenpathologie und Electrotherapie," 1874, p. 98) had expressed the opinion that crossed reflexes due to electrical stimulation of one side of the body, paralyzed or unparalyzed, occurred only in connection with lesions of the pons Varolii. This view was opposed by Brenner ("Electrotherapie," B. ii., pp. 175, 241, 1869), who reported cases in which, together with increased irritability to both galvanism and faradism of the muscles involved in peripheral facial palsy, reflex contraction of muscles upon both the paralyzed and the unparalyzed side took place, the muscles on the paralyzed side contracting in response to currents that induced no movement in the muscles of the unparalyzed side. The contraction became the less marked the more closely to the ear the electrode was applied. This peculiarity was attributed to diffusion of the current, acting upon the more irritable muscles of the paralyzed side. When the current strength was increased to such a degree that contractions occurred on the unparalyzed side, those on the paralyzed side were submerged. An observation in which, in a case of peripheral facial paralysis, contraction of the muscles upon the unparalyzed side took place on stimulation of the muscles on the paralzyed side, is recorded also by Rosenthal ("Handbuch der Diagnostik und Therapie der Nervenkrankheiten," 1870, p. 22; "Electrotherapie," 1873, p. 295). Petrina (*Prager medicinische Wochenschrift*, 1880, Nos. 39 and 40) has reported a case probably of disease of the pons, and Senator (*Archiv f. Psychiatrie*, B. xiv., p. 643) one shown by autopsy to be such, in which this reflex facial contraction was noted. Other observers have described an analogous phenomenon in other parts of the body in association with other conditions.

From a consideration of all of the evidence, Bernhardt reaches the conclusion that in isolated cases of either central or peripheral facial paralysis, on electrical stimulation of both the paralyzed and the unparalyzed side, so-called reflex movements occur upon the unstimulated half of the face. Although it is probable that this, is more common in the presence of pontine than of other cerebral lesions, it occurs also in connection with peripheral facial paralysis. A discrimination between the central and the peripheral seat of the lesion is not to be based upon the presence or absence of this symptom. Its presence is not related to the preservation of sensibility on the affected side of the face. The mode of origin is not clear in a large number of cases. In some, particularly when degenerative reaction is present, it is clearly not reflex, but is probably due to diffusion of the current. In a smaller number, without degenerative reaction, it is also due to diffusion. Further, in some cases dating from early life, and probably congenital, contraction especially of the muscles near the median line of the chin and the lower lip occurs on stimulation of the healthy side, in consequence of the passage of healthy muscle fibres from the unaffected to the paralyzed side. Finally, there are cases dating from birth or early life in which stimulation of the muscles on the healthy side causes contraction only on the opposite side, even when the irritability of the muscles on this side is diminished, and for which an explanation is yet wanting.

NEW JERSEY BOARD OF EXAMINERS, AND MEDICAL LICENSES FROM OTHER STATES.

In the annual report of this board, recently issued, is the following statement:

During the past year this board has taken an advanced step in the direction of interstate reciprocity of medical licenses. This problem has been discussed in the meetings of the National Confederation of State Examining and Licensing Boards for several years past, with but little progress toward its solution. State sovereignty forbids the establishment of a national examining and licensing board whose certificate would confer the right to practise in all the States. The question, therefore, naturally reverts to State medical boards and to their securing such legislation as will make the minimum academic and medical requirements, and the kind and grade of State examination, equal, or substantially the same, in the different States. When this unity of action and aim is attained, reciprocity of medical license between the States can be justly adopted. The preliminary requirements of this board, as previously stated, the grade and scope of the examination, and the average percentage required, secure a State license, fully meet, it is believed, the demands of the State in the protection of its citizens from incompetent and fraudulent practitioners of medicine, and the interests of the profession in uplifting and maintaining its highest standards. With these objects secured, this board desires to extend every professional courtesy to licentiates of other State examining-boards whose requirements and examinations are substantially the same as those of this board. To meet this end, this board, at the annual meeting in July, decided to endorse the certificate of examination and license of any State examining and licensing board in the United States, in lieu of an examination, under the following conditions:

1. That the academic education of the candidate meets the requirements of this board.

2. That the candidate's period of medical study meets the requirements of this board.

3. That the candidate must have passed a State medical examination of substantially the same grade and kind as that required by this board, and must have been duly licensed.

4. That the candidate must have obtained a general average of not less than seventy-five per cent. in the subjects examined.

The action of the New Jersey State board of medical examiners is progressive and enlightened. Interstate reciprocity of medical licenses must come sooner or later throughout the United States. The times, however, are not altogether ripe for this event, so that other means must be devised to better the situation, until the whole country has agreed upon a satisfactory *modus operandi*. The plan arrived at by the Jersey board appears to be a workable and unselfish interim method of clearing up the difficulty. The most gratifying phase of the question is that such a movement is likely to create a feeling of emulation and incite other States to similar efforts to improve the standing of the medical profession in all parts of the United States. Pending the introduction of universal interstate reciprocity, a general interchange of licenses will be a great advance in that direction.

News of the Week.

The Middleton Goldsmith Lecture of the New York Pathological Society will be delivered at the New York Academy of Medicine, No. 17 West 43d Street, on Tuesday evening, March 26th, at 8:30 o'clock, by Prof. Charles Sedgwick Minot, M.D., professor of histology and human embryology, Harvard Medical School. The subject is: "The Embryological Basis of Pathology."

American Academy of Medicine.—At a well-attended dinner given at Philadelphia on March 16th by fellows of the American Academy of Medicine of that city and its vicinity, addresses were made by Drs. S. D. Risley, Charles McIntire, G. Hudson Makuen, W. W. Keen, and others on the objects of the Academy, and it was agreed to form a local branch, to meet in the intervals between annual meetings and in other ways foster the spirit and promote the aims of the academy.

Attendance at Swiss Universities.—The number of medical students is decidedly on the increase, without any obvious reason in the way of demand. The number of medical students for the winter term, 1900-1901, amounts to 1,375, thus distributed among the different universities: Basle, 145; Bern, 388; Geneva, 357; Lausanne, 183, and Zurich, 302. The number of women, especially of foreign women studying medicine in Switzerland, has greatly increased. Of these the Russian female students are the most numerous, comprising 47 per cent. of the whole. Only 21 are of Swiss nationality.—*Lancet.*

Spread of Smallpox in Scotland.—The outbreak of smallpox in Scotland continues to spread and to occasion grave concern to the health authorities. Cases are reported from a large number of districts, mostly in the western and central counties, but the wide range which the outbreak has attained can be appreciated from the fact that the disease has appeared in places so widely separated as Dundee, Fifeshire, Morayshire, and Dumfriesshire. Everywhere the sanitary officials are exercising the utmost vigilance to check the further spread of the epidemic. A very large proportion of the cases in other districts can be traced to Glasgow, where, notwithstanding certain fluctuations in the returns from day to day, the increase in the number of cases has been steady.

Physicians in Canadian Parliament.—Eighteen doctors have been elected members of the new Dominion parliament. Among the few conservatives who escaped the landslide, we are gratified to see the name of Dr. Roddick. It would have been a distinct loss to the medical profession of Canada had he been defeated, especially when the efforts to establish a licensing board for the Dominion are within a reasonable distance of success. Dr. Roddick has given much time and has shown energy and ability in overcoming the difficulties in the way of this scheme, and has rendered a public service in the interests of not only the medical profession but the community at large, deserving the highest praise.

The Period of Incubation of Yellow Fever.—Dr. H. R. Carter, surgeon of the Marine-Hospital service, writes:

"Please do me the favor to publish this emendation to an article of mine—'The Period of Incubation of Yellow Fever'—which appeared in the MEDICAL RECORD of the 9th instant:

"In the table of cases under Class III., *i.e.*, cases which, having had only a single exposure to infection, give a definite period of incubation, are four cases of one family, Mr. L——'s, at Taylor, Miss.; giving intervals of eight and eight and one-fourth days between the recognized exposure and the development of the disease. In giving the details of these cases the writer stated that they would be considered doubtful, and hence not considered under the principles which had obtained in selecting the others, and he gave reasons why he judged best to admit them to record. Since then an examination of the locality shows that Mr. L——'s house was only one hundred yards from a station house, then abandoned because two cases of yellow fever had developed there a short time before. This is too close to be excluded as a source of infection for Mr. L——'s family; and, taking it into consideration, the claim that the exposure of these people on August 3d was the only exposure to which they were subjected—and hence the infecting exposure—although from attendant circumstances probable, becomes doubtful, and these cases should not have been included as certainly in Class III.

"This class then gives twelve cases with incubation of from three to five and three-fourths days—one only reaching (two exceeding) five days."

The Medical Course of the University of Pennsylvania.—Provost Harrison, of the University of Pennsylvania, calls our attention to a misunderstand-

ing of his recent report concerning the length of the medical course. He writes: "As a matter of fact, the action which the trustees of the University have taken, upon recommendation of the faculty of medicine, has been to require a full four-years' course—abolishing admission to the second year of the medical course, of college graduates in arts and science who had fulfilled certain requisites; and the rule to which my report referred, and which will take effect with the beginning of the session, September 1, 1901, is as follows:

"'Any graduate in arts or science of a college (recognized by this University), who has completed the studies of the first year of the medical course, viz., chemistry, elementary anatomy (with special reference to histology, osteology, syndesmology, and myology), physiology (excepting heat mechanism and nervous system), or bacteriology, or any one of them, as detailed under the heading "Outline of the Course" on p. 47 of the "Medical Department Catalogue"; and who has passed satisfactorily the examinations given by the professors of the respective branches in this medical school—may be excused from that portion of the study given in the first year of the course, provided that he utilize the time scheduled for that study in advanced work in chemistry, anatomy, physiology, or bacteriology, according to his preference and capabilities, or in anticipating work of the second year, in so far as the official roster will permit.'

"It will be observed that, while the requirement of four full years is still imperative, as is demanded by the present status of medical education, provision has thus been made for avoiding duplication of work."

The Low Death Rate of Havana.—According to the recent report of Dr. W. C. Gorgas, chief sanitary officer of Havana, the deaths in the month of February have been fewer than in any February of which there is any record, the minimum being that of 1893, when there were 446 deaths, and the maximum that of 1898, when there were 1,602. This is not only less than for any February since 1890, but actually less than for any month of the preceding twelve years, the lowest in any month being 444 deaths, in November, 1900. The average for the ten years succeeding 1890 was 746 deaths. The rate per thousand—19.32—makes even a better showing. The last February of the Spanish rule, 1898, gave a death rate of 82.32 per thousand; February of 1901—the third February under American rule—a death rate of 19.32. This is a very creditable death rate, and places Havana in the class of healthy cities of the world. Many of the cities of the United States and Europe have a higher mortality rate than this. According to the latest figures from the Marine-Hospital reports, Baltimore, with a population of 334,489, for the week ending January 26th, had 225 deaths—a death rate of 26.93; Cincinnati—population 326,000—for the week ending January 25th, had 142 deaths—death rate 22.65; Boston—population 560,892—for the week ending January 26th, had 260 deaths—death rate 24.10; Jacksonville—population 17,201—for the week ending January 19th, had 16 deaths—death rate 48.37; Newark, N. J.—population 246,070—for the week ending January 19th, had 107 deaths—death rate 22.61; New Orleans—population 287,000—for the week ending January 19th, had 156 deaths—death rate 28.26; New York—population 3,437,202—for the week ending January 26th, had 1,432 deaths—death rate 22.42; Washington—population 278,719—for the week ending January 19th, had 141 deaths—death rate 26.60; Belfast, Ireland, for the week ending January 5th, had 165 deaths, with a death rate of 23.90; and Mobile—population 38,469—for the week ending January 16th, had 22 deaths—death rate 29.73. It will be seen that most of the cities have a much higher death rate than Havana. Jacksonville, Mobile, and New Orleans, all have a higher death rate than Havana, and there can be no doubt that we would find such to be the case with other Gulf cities if we could get statistics on the subject. At present they look upon Havana with suspicion, but in the near future, Havana will have to guard against them. Taking cities in the yellow-fever area, such as New Orleans, Mobile, Pensacola, Tampa, Key West, and Havana; those in bad sanitary condition, as shown by their high death rate, would be more likely to become infected than a city such as Havana, which is in first-class condition, as shown by its low death rate. During February of 1900, there were 17 new cases of yellow fever; in February of 1901, 8 new cases. As the number of non-immunes was very much larger in February of this than in that of last year, the showing is thought to be very encouraging. Besides disinfecting the houses with formalin and other disinfectants, the rooms occupied by a yellow-fever patient are screened, as soon as his case is reported, and all the mosquitos in the building are killed with the fumes of pyrethrum powder, at the same time that all places where mosquitos can breed about the building are covered with kerosene oil. The mosquitos are also killed in all the adjoining buildings in the same way. With these measures and the steps being taken to kill the mosquitos in the suburbs, Dr. Gorgas hopes to decrease the yellow fever during the coming summer.

The New York Medical Society for Clinical Research.—A society bearing this name has just been organized, with the object of encouraging young physicians in thorough clinical work and original research. To further these purposes, a library and laboratory have been established wherein the members may do their special work. The officers for the ensuing term are: *President*, Dr. Gutman; *Vice-President*, Dr. Mandel; *Secretary*, Dr. Lubman; *Treasurer*, Dr. Spirac. Any person who is a duly licensed regular practitioner is eligible to membership.

Pathological Society of Philadelphia.—At a stated meeting held March 14th, Dr. Joseph McFarland presented a communication on "Snake Venom," detailing a series of experiments directed to the production, according to the methods of Calmette, of an anti-venom that should be protective against the poisons of American snakes. Dr. David L. Edsall read a paper entitled "Carbohydrates of the Urine in Diabetes In-

sipidus." Dr. W. M. L. Coplin described "A Convenient Method of Staining a Number of Sections on One Slide," and also "A Modification of the Staining Methods of Claudius and Van Gieson." Dr. Müller presented a specimen of "Multiple Aneurism of the Aorta," from a man thirty-seven years old, in whom death resulted from catarrhal pneumonia. A saccular dilatation was present at the junction of the ascending and transverse portions of the arch of the aorta, and another at the junction of the transverse and the descending portions of the arch.

Louisiana State Medical Society.—The next meeting will take place in New Orleans, April 18, 19, and 20, 1901, and the sessions will be held, as usual, at the Medical Department of Tulane, on Canal Street.

The American Laryngological, Rhinological and Otological Society.—The seventh annual meeting of the American Laryngological, Rhinological and Otological Society will be held at the New York Academy of Medicine in the city of New York, May 30, 31, and June 1, 1901.

Large Gift to a Medical College.—John Du Bois, of Du Bois, Pa., has given $1,000,000 to Dunham Medical College. The officials of the college say that the gift comes as a thank-offering for benefits received by his wife in treatment by members of the college.

Defeat of Undesirable Legislation.—A bill to amend the law by which the bodies of those dying in public institutions can be claimed for burial only by relatives has just been defeated in the Pennsylvania Legislature. The object of the amendment was to extend the privilege of claim to "friends," and its passage would have deprived the anatomical board of many subjects that it now receives and needs for dissecting and teaching purposes.

Philadelphia Pediatric Society.—At a stated meeting held March 12th, Dr. J. A. Scott read a communication on "Intestinal Sand." After referring to the paucity of the literature on the subject, including that of cases in which the material consisted of elements derived from the food, he exhibited two specimens obtained from adults and one from a child most carefully nourished. Dr. George McClellan delivered an address on "The Anatomy of Childhood," illustrated by original photographs, preparations, and lantern slides.

College of Physicians of Philadelphia, Section on General Medicine.—At a stated meeting held March 11th, Dr. D. J. Milton Miller exhibited "A Case of Spleno-myelogenous Leukæmia, with a greatly Enlarged Spleen." Dr. William G. Spiller presented "A Case of a Typical Disseminated Sclerosis" occurring in a man who exhibited static ataxia and in-co-ordination of gait, with exaggerated knee jerks, some thickening of speech, and a history of nystagmus and diplopia, without sensory changes, Babinski reflex, or a history of syphilis. The possibility of cerebellar ataxia was considered. Dr. David Riesman presented a communication entitled "Primary Tuberculosis of the Pericardium," reporting a case in which this lesion was diagnosticated during life and found after death. The appearances were not characteristic, but their tuberculous character was disclosed both on histological examination and by animal inoculation.

Count Tolstoi Dangerously Ill.—The world-renowned Count Tolstoi, the great Russian novelist, is reported to be suffering from Bright's disease.

Dr. Heinrich Stern has been elected Professor of Internal Medicine in the New York School of Clinical Medicine.

Isolation Hospital Destroyed by Mob.—The building which was erected at Orange, N. J., by the health authorities as a pest house for the accommodation of smallpox patients was destroyed by a mob on Monday morning.

Medical College Destroyed by Fire.—Fire on Sunday destroyed the college of medicine and the literary-department buildings of the University of Iowa. The loss is estimated at $250,000.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the week ended March 16, 1901. Surgeon O. Diehl ordered to the *Indiana* March 15th. Assistant Surgeon R. K. McClannahan detached from the *Indiana* and ordered home to wait orders for sea duty. Assistant Surgeon O. M. Eakins, resignation accepted, to take effect April 15, 1910. Pharmacist E. T. Morse detached from the Boston navy yard and ordered to the *Michigan*. Pharmacist I. N. Hurd detached from the *Wabash* and ordered to the Boston navy yard.

Obituary Notes.—Dr. William Dexter Anderson, a prominent physician of New Haven, died on Friday, March 8th, as the result of an operation. He was sixty years of age, and was graduated from the Yale Medical School in 1865. In his younger days he was a musical composer of promise, but never had any of his works published.

Dr. Alonzo T. Smith, the oldest alumnus of the Geneva Medical College, died in Syracuse on Friday, March 8th.

Dr. John B. Busteed died on Monday, March 11th, at the Consumptives' Home in Brooklyn, aged thirty-one years. He went to Corea as a medical missionary of the Methodist Church in 1893 and returned to Brooklyn in 1897.

Dr. Dudgeon, who died recently in Pekin, was perhaps the best known of all the Europeans in China, with the exception of Sir Robert Hart. Dr. Dudgeon went out early in the sixties to take charge of the British Legation Hospital, and the walls of the hospital were adorned with tablets testifying to his surgical skill. For twenty years the doctor was daily at his post, receiving all sorts and conditions of Chinamen, and at times his patients numbered one hundred a day. He had the confidence of the best Chinese statesmen and knew all about the inner working of the strange celestial machine.—*Evening Post.*

Progress of Medical Science.

New York Medical Journal, March 16, 1901.

The Specific Treatment of Acute Dysentery.—W. J. Cruikshank believes that we have in sulphate of magnesium, when properly administered in acute dysentery, a remedy which approaches as nearly to a specific as quinine does in the treatment of true malarial infection or mercury and iodide of potassium do in syphilis. In all cases of acute dysentery, from the beginning of the attack until there is a subsidence of all the symptoms, the remedy should be administered in drachm doses every three hours, dissolved in one or two ounces of distilled water, to which may be added ten drops of the dilute sulphuric, or aromatic sulphuric, acid. Experience has proved conclusively the unprecedented results which may be obtained from the use of this drug in the manner described. The beneficial effects are shown in a very few hours after the commencement of its use, and in from twenty-four to forty-eight hours the patient's condition shows marked general improvement; the pain becomes less, the tormina and tenesmus rapidly subside, and there are diminution of the pulse rate and lowering of temperature. If tympanites is present, it is rapidly reduced; the stools become less painful and less frequent, the blood and mucus disappearing. At the end of forty-eight hours, in the vast majority of cases, the stools take on a biliary character. The treatment must now be continued steadily until the stools become nearly normal. When this result is obtained, the medicine may be gradually withdrawn. The average time required for the establishment of convalescence is from three to six days from the commencement of the attack.

Angeioma Cysticum of the Nose.—By H. L. Wagner. Two cases are reported, one in a boy aged nine years, and the other in a woman aged twenty-eight years. Sections of the cyst wall showed a columnar ciliated epithelium covering nearly the whole of the external part of the growth, with the exception of a certain portion which consisted of squamous epithelium, produced either by pressure or by continuation of the mother stratum. No glands were found. There were a large number of veins, some of them enlarged, running parallel with the sac, and also some large venous sinuses. The fluid contents of the cyst were alkaline in reaction, with a specific gravity somewhat lower than that of blood-serum, and of a brown color. The chemical analysis revealed the common elements of blood.

Congenital Dislocation of the Shoulder with Report of Two Cases of Dislocation Posteriorly.—By D. W. Marston. A continued article.

Substitute Feeding of Infants upon Milk Modified According to Prescription in Laboratories.—By W. P. Northrup.

The Pathology of Intra-Uterine Death.—By Neil McPhatter. A continued article.

The Representation of Biliary Calculi by the Roentgen Rays.—By Carl Beck.

A Simple Apparatus for Modifying Cow's Milk.—By C. Herrman.

Medical News, March 16, 1901.

Observations upon the Amœbæ Coli and their Staining-Reactions.—Charles F. Craig states that the amœba is a round, oval, or irregular protoplasmic body, varying in size; motile or immotile, the motility being amœboid in character and, when present, being generally moderate; pale or faint green in color; refractive, with sharply cut border, and containing a circular or oval, lighter-colored space, known as a vacuole. In some a darker colored nucleus can be distinguished, and in the immotile organisms a darker-colored, central or eccentric portion, containing the vacuoles and comprising the greater part of the parasite, and known as the endoplasm, can be seen, surrounded by a narrow or much smaller layer, lighter in color and clear, known as the ectoplasm. The method of reproduction of the parasite is generally believed to be by sporulation. In all of the staining solutions that the writer has used, he has found only three that are worthy of use: Loeffler's methylene blue solution, carbolic fuchsin solution, and thionin solution. Of these, the first is the quickest and best stain for general use, while the carbolic fuchsin is by far the best when it is desired to stain the nuclens or nucleolns, as well as certain peculiar bodies within the protoplasm of the amœba. Toluidin blue is also a good stain. The smears are stained in the methylene blue solution for from three to eight or ten minutes; about five minutes gives the best results; the smears are then washed in distilled water and mounted in Canada balsam. Degeneration of the amœbæ takes place in two ways, *i.e.*, by vacuolization and by fragmentation.

A Report of Three Cases of Thoracic Aneurism Treated by Subcutaneous Injections of Gelatin.—Lewis A. Conner, after reporting these cases, recapitulates: Of the three patients, two received three injections and one, seven. In two cases the injections had to be discontinued because of the severe local pain. In the third the pain was only slight. In one case, in which seven injections were given, a very slight improvement could be detected. In one case a slight increase in symptoms was noted, while the third patient died of rupture of the aneurism while under treatment, and the autopsy showed no evidence of recent thrombus formation, although the condition, that of a large sac with a small communication with the aorta, was an especially favorable one for clotting. Aside from the pain and local irritation no untoward symptoms were observed in any of the cases, as a result of the injections. The writer adds that he is not ready to conclude from these cases that the method has no therapeutic value, since in none of these cases was it possible to carry out the treatment fully. His experience has convinced him that, whatever the curative value of the treatment, its usefulness is seriously impaired by the severe pain which frequently follows the injections.

A Preliminary Note on the Relation of the Form of the Tubercle Bacillus to the Clinical Aspects of Pulmonary Tuberculosis.—By Henry Sewall.

The Treatment of the Heart in Typhoid Fever and Other Infectious Diseases.—By Albert Abrams.

Recent Experiences with Erythromelalgia.—By Henry L. Elsner.

Rhinoscleroma.—By H. Jarecky.

Philadelphia Medical Journal, March 16, 1901.

A Contribution to the Technique of the Widal Test.—A. Robin elucidates the following problems which present themselves: (1) The dilution. (2) The best way of obtaining a motile culture free from "natural" clumps. (3) The differentiation between a true and a pseudo-reaction. (4) The time limit. There should be high dilution (1:20 to 1:40), since bacteriologists have observed that the difference between normal blood and that of typhoid patients is one of degree and not of kind. The writer then describes an appliance for drawing up one drop of blood, which is both accurate and simple. This method is essentially a modification of Cabot's medicine-dropper method. In order to obtain a motile organism, one needs only to get from a bacteriologist a pure culture of typhoid bacilli, well tried as to their motility. The writer uses a combination of both the bouillon and agar cultures. An agar culture is made and placed in the incubator, or kept at room-temperature for twelve to eighteen hours, when either two or three loopfuls are transferred into bouillon until a marked turbidity results, or a small quantity of bouillon is added to the agar culture, and enough of the growth scraped off to produce a uniform cloudiness. By this method the natural clumps, so frequently observed in bouillon cultures, are entirely avoided. To insure still further against error, a slide with two concavities is employed; on each of two cover glasses is dropped a loopful of the cultures; on one, the blood diluted 1:20 to 1:40, while the other serves as a control. The Widal test can generally be more satisfactorily performed with an oil immersion. As to the time limit which determines a positive reaction, the author proposes the following: Dilution, 1:10; time limit, five to fifteen minutes; 1:20, fifteen to thirty minutes; 1:40 to 1:100, thirty to sixty minutes; 1:100 to 1:200, one to two hours; that is, if within the specified time a considerable number of bacilli are found actively motile, or, if dead, fail to arrange themselves in clumps, the reaction is to be pronounced negative, irrespective of the clumps which have already formed.

Removal of the Right Upper Cervical Sympathetic Ganglion for the Relief of Glaucoma Simplex.—D. H. Coover reports the case of a man aged sixty-five years, upon whom this operation was performed. The immediate results of the operation were very encouraging, and were as follows: Tension was lowered to almost normal. There were contraction of the pupil and slight reaction. There was increase of the visual field and of visual acuteness, and the temporal field or nasal side of the retina improved, while the nasal field or temporal side of the retina did not improve. These conditions remained until an attack of supposed "cold in the eyes," which proved to be nothing more than the return of the former disease, glaucoma. The writer believes that the operation is of no service in glaucoma simplex when vision has been reduced to zero, as the final outcome of this case demonstrates, but may be of service in arresting the disease in the earlier stages and in retaining vision before atrophic changes have taken place in the nerve, retina, and choroid. After myotics and iridectomies have failed to relieve the disease, it is then that we are justified in advising sympathectomy in hope of relief from permanent blindness. Even then there is no assurance that the glaucomatous attacks will not return months afterward. The operation when performed by an expert is not dangerous.

Strangulated and Gangrenous Hernia; Kelotomy and Laparotomy in Strangulation, External and Internal; Artificial Anus; Enterostomy, Primary or Secondary Resection; Enterectomy, and End-to-End or Lateral Jointing in Gangrenous Hernia.—By Thomas H. Manley.

A Synoptical Report of One Thousand One Hundred and Forty-one Cases of Indigent Visitors Treated at Hot Springs, Arkansas.—By Howard Paxton Collings.

Rupture of the Rectum and Hernia of the Intestines in an Insane Man.—By A. R. Moulton.

Percentage and Laboratory Feeding.—By J. P. Crozer Griffith.

The Boston Medical and Surgical Journal, March 14, 1901.

A Case of Cæsarean Section.—Herbert J. Keenan reports a case operated on in very poor surroundings. An oil lamp on the wall supplied light; the instruments used were those of the ordinary pocket case. There was very little bleeding, only one snap being used. The child and placenta were delivered in less than five minutes; the abdominal wound was closed, and the patient in bed in less than fifty minutes. The post-operative period was unimportant till the sixth day, when, after a fit of coughing, the wound was opened its entire length, with the escape of intestines. Under chloroform the bowel was replaced, the edges of the wound were brought together, and again closed. Mother and child did well subsequently.

Intestinal Anastomosis.—Charles G. Cumston gives a survey of the work done in this line by the older surgeons. Ambroise Bertrandi, in 1769, writes of introducing into the gut a piece of calf's trachea, which had been dried, softened in hot alcohol, and covered with Peruvian balsam, and pulling the divided ends of the intestine over it, suturing them, and abandoning the whole to nature. On the twentieth day a ring of the trachea was found in the fæces, and on the fortieth the patient was entirely cured. Fabricius d'Aquapedente states that some surgeons employ cylinders of elder wood, or the trachea of certain animals, but he condemns their use in intestinal anastomosis.

Sudden (Apoplectiform) Bulbar Paralysis; Hemiplegia; Astereognosis.—W. E. Paul describes a case, the peculiarity of which lies in the mode of onset, the most common type of bulbar paralysis being of insidious origin and gradual progression. In this case there was apoplectiform onset and bilateral lesion, with improvement in the bulbar symptoms for the first two months of the palsy. There is, of course, danger of further degenerative changes, which may begin at any time.

The Story of the Boston Society for Medical Improvement.—By J. G. Mumford.

The Lancet, March 9, 1901.

Pure Urea in the Treatment of Tuberculosis.—By Henry Harper. The author noted the fact that from the family histories of many of his patients it was evident that families showing a marked tendency to gout, gravel, and calculus rarely suffered from tuberculosis. In contradistinction to this fact, families who chose to live largely on farinaceous foods—who were, in short, bad meat eaters—presented frequent tuberculous infection. He also noted the frequent occurrence of tubercuIosis and glycosuria in the same patient, and is inclined to attribute it to the fact that the chemical composition of the urine has a direct relation to the growth of the tubercle bacillus in the body, and that a certain immunity is conferred by urea and uric acid. His impression is that, if we can saturate the body with urea or uric acid, these, in combination with bodily fluids other than the urine, will act as an antitoxin to the bacillus. Acting on this theory he has given urea in doses of gr. xx. four times daily, and his results are sufficiently encouraging to lead him to persist in its use. He does not neglect hygienic and tonic adjuvants. Nine cases are given with some detail. All showed the presence of the bacilli. The effect is, of course, best seen in cases with an absence of mixed infection.

A Case of Pemphigus Neonatorum in an Infant Three Days Old.—By C. J. Glasson. The birth of the child was normal, and it seemed perfectly healthy. On the third day bullæ appeared, round in shape, filled with a cloudy fluid, and surrounded by a bright-red ring of inflammation. On the fourth day the body was pretty generally involved, and in addition to the local lesions there were present the usual features of a general febrile disturbance. Each bulla was opened with an antiseptic needle, the contents were removed by gentle pressure with absorbent cotton, the child was placed in a bath of warm rain-water and dried by gentle application of soft linen. Boric-acid ointment was applied to each affected area. In three days the child had nearly recovered, and the ointment was changed to one of zinc oxide, made with benzoinated lard. On the ninth day the whole skin began to peel off like a glove, leaving the cutis vera red and weeping and the papillæ prominent. A dusting-powder was then used, made of zinc oxide, finely powdered starch, with a small portion of camphor. Perfect recovery ensued.

A Few Cases of Ethyl Chloride Narcosis.—By W. J. McCardie. The author commends the use of this agent instead of nitrous oxide, as a preliminary to etherization. From five to six cubic centimetres of the chloride are necessary. Anæsthesia is induced in about two minutes and as rapidly passes off, leaving no, or at most only slight, after-effects. The drug has no irritating action, and can be administered in heart, lung, or kidney cases, in which ether or chloroform are either contraindicated or are dangerous. Its main disadvantage is that, except perhaps in children, muscular relaxation is generally not quite complete, and rigidity may be marked in muscular, and especially in alcoholic, subjects.

A Further Note on the Production of Local Anæsthesia in the Ear, Nose and Throat.—By A. A. Gray. Two solutions are prepared, one of a fifteen to twenty per cent. solution of eucaine in anilin oil, and one of a twenty-per-cent. solution of cocaine in rectified spirit. Ten minims of each are mixed together, the mixture being at first opalescent but later becoming clear. The maximum amount of the mixture to be used at one sitting is twenty minims. This amount the author has found to be quite sufficient for painless excision of tonsils, removal of spurs on the septum, cauterizing, and other similar operations. Seven minutes should elapse between the application and the commencement of work. The application is to be made by the usual cotton carrier.

The Statistics of Gastric Ulcer with Special Reference to Gastric Hemorrhage, its Frequency and its Fatality.—Clinical lecture by Byrom Bramwell. The author gives certain statistics of the conditions mentioned, and takes exception to the statistical conclusions of Mayo Robson on the same topic, recently published in *The Lancet*.

Two Cases Illustrating the Use of the X-Rays in Surgery.—By G. T. Holland. Case I. was that of a boy who received a gunshot wound of the eye, and Case II. that of a boy who accidentally swallowed a tooth-plate. The exact location of the foreign bodies was easily demonstrated.

Remarks on a Case of Electric Shock.—Henry Smurthwaite reports this case of a man aged twenty-nine years, who received a shock from a machine called a "rectifier." In his right trousers pocket there was a large bunch of keys, and with his right thigh he was leaning against the brass socket which was attached to the switch by brass nails which were too long, making contact with the high-pressure terminal inside. He was about to adjust the brushes on the motor with his right hand, when he felt the shock. In this position he was completing a circuit: from alternator to rectifier commutator, water-contact switch, brass socket, keys, right thigh, through the body to his right hand, and thence to the windings in the small motor. The keys were undoubtedly the indirect cause of the accident. The large amount of high pressure of electricity passing through the body, and which did not cause death, was 2,150 volts. Besides its high voltage, the current was alternating. Some authorities believe that this renders the chance of a fatal termination more certain. When brought to the hospital, the man was in a very collapsed condition. He was given a capsule of amyl nitrite by inhalation, and a few minutes later a hypodermic of strychnine. At the same time the lower limbs were massaged and hot-water bottles placed to the trunk. In seven and one-half hours he had completely recovered from the shock. After recovery, he never had an ache or a pain, or the slightest mental trouble.

Vulvo-Vaginal Thrombus.—V. Bué reports the case of a girl aged seventeen years, whose first labor lasted forty-three hours. Aside from the length of time there was nothing to call attention to the case. Immediately after the expulsion of the fœtus the patient complained of a very sharp pain in the internal surface of the left labium majus. On examination there was discovered a small spot, slightly bluish and painful to the touch. About two hours after delivery the labium was swollen to the size of a hen's egg. There were frequent cramps in the lower extremities. Compression was applied, which only increased the pain, while it did not arrest the rapid increase of the blood tumor. When the swelling had reached the size of a fist, the antero-lateral part of the left side of the vagina was seen to be swollen. The mucous covering of the tumor had become almost black. The whole mass was very hard. The swelling, after reaching this stage, seemed to remain stationary, when suddenly there came a gush of blood. With this occurrence the patient experienced great relief. The flow of blood continued until the patient showed the untoward effects of hemorrhage. The writer, being called at this time, decided on immediate intervention. The thrombus was opened by a vertical incision of about 7 or 8 cm., starting from the point of spontaneous opening. The wound was emptied of its contents, disinfected, and packed with iodoform gauze; the vagina was also packed with gauze and bandaged. On the fourth day the elevated temperature fell to normal, and on the tenth day the patient was well. The diagnosis of vulvo-vaginal thrombus is easy, but its occurrence is rare. On the average, hæmatoma of the vulva and vagina is met with once in about two thousand three hundred and seventy-five labors.—*Le Nord Médical*, February 15, 1901.

Cardiac Troubles of Gastric Origin.—According to Bonnaymé, this affection is far less rare than is generally thought. The symptomatology of these troubles is varied. The patient is conscious of the beating both of the heart and of the abdominal aorta, both of which are observed especially during digestion. Again there may be palpitation of the heart or a sensation of cessation of the heart-beat. Huchard describes pain resembling that of angina pectoris. Irregularities and intermittences have been noted, as well as slowing of the pulse. According to some authors, tachycardia is the trouble most frequently observed. It may be either paroxysmal or permanent. All authorities do not admit the acute dilatation of the heart which others have studied. Asystole is exceptional. Most writers admit syncope. The diagnosis has for its principal object the establishment of the relation between the cardiac troubles observed and the gastric lesion underlying them. The pathogeny of these troubles has provoked much discussion. The facts appear rather to confirm the mechanical theory. The nervous action ought not, nevertheless, to be neglected. The prognosis is most often very favorable. As to the treatment of these cases, if after most careful examination the physician is convinced that the origin of the trouble is in the stomach, then the remedies proper to the particular condition discovered should be applied and the stomach should be the organ treated, not the heart.—*Gazette des Hôpitaux*, February 11, 1901.

Practical Prophylaxis against Tuberculosis.—Samuel Bernheim, in speaking of tuberculosis among soldiers, gives the principal points which St. Kovatcheff presents in concluding his thesis: (1) The use of hygienic measures suitable to prevent the propagation of the bacillus: (*a*) to collect and destroy the sputum, (*b*) to suppress dust by sweeping with damp brooms, (*c*) nocturnal ventilation. (2) The rejection at the time of enlistment of all the young men who are in the least affected by this disease, or who are even suspected of being so. (3) The temporary suspension of all the soldiers who during their service have had a pleurisy. (4) The provision of places of suitable temperature for use in the changing of garments, for eating, for recreation, and for exercise. (5) The diminution of work or the subdivision of recruits into two groups according to thoracic capacity and general development. (6) The variation of the alimentary *régime* and suppression of the sale of alcohol. (7) The construction of military sanatoria suitable for the treatment of poor tuberculous soldiers. (8) The progressive establishment of barracks outside of the large towns, where a combination of circumstances favors ill-health of the troops.—*La Tribune Médicale*, February 20, 1901.

Cholecystitis in the Guise of Appendicitis.—Adenot concludes that cholecystitis may be confused with appendicitis rather frequently, but the inverse error of diagnosis ought to be very rare. Whenever one would have to suspect the diagnosis of appendicitis if the symptoms are not clear, it would be necessary to think of the possibility of cholecystitis. The displacements of the gall bladder are a serious cause of error in diagnosis in cholecystitis. The history is very important in the diagnosis of cholecystitis. The gall-bladder tumor, and the situation of the most severe pain, are the important signs, but they ought to be corroborated by the other symptoms habitual to cholecystitis. Acute peritonitis, secondary to cholecystitis, is not rare. One must always think of the possibility of this origin in generalized peritonitis from perforation. Angiocholecystitis and the perforations resulting therefrom can be confounded in typhoid fever with appendicitis and peritonitis from intestinal perforation. The diagnosis of cholecystitis as the origin of peritonitis presents a case most important for intervention.—*Lyon Médical*, February 24, 1901.

Berliner klinische Wochenschrift, Feb. 25, 1901.

A Hitherto Unknown Variety of Uterine Stenosis.—L. Landau narrates the history of the case of a woman aged forty years, who had never menstruated, but who ever since her twelfth year had complained of monthly attacks of pelvic pain and discomfort. She had had some operation for relief of the trouble, but without avail. Examination showed the existence of double hæmatometra and hæmatosalpinx; also the presence of a group of tumors which seemed to fill the entire pelvic basin, so a laparotomy was performed and the uterus with the adnexa removed. There were found to be a hæmatometra of the uterine body, double hæmatosalpinx, right-sided productive öophoritis, hemorrhagic cystoma of the left ovary, adhesive pachypelvic peritonitis, and hemorrhagic cystoma of the pelvic connective tissue. But the most interesting condition was that of occlusion of the uterine canal by a round mass the size and shape of a small apple, solid in structure and occupying the position of the cervix, thence extending diffusely over the uterine body. It proved to be an adenomyoma of the mesonephrou, or primordial kidney. This type of tumor has been described by von Recklinghausen, a short exposition of whose views is given by the author. The author considers it remarkable that a patient could have suffered from such a condition for so long a time without the occurrence of disastrous consequences.

Aortic Aneurism Presenting the Clinical Picture of a Solid Mediastinal Tumor.—C. A. Ewald's patient was a woman aged forty-three years, who presented the various signs and symptoms of a mediastinal tumor pressing on the various structures at the root of the neck. She finally died during an attack of dyspnœa, and the autopsy revealed an aneurism the size of the fist, occupying the ascending and part of the transverse arch of the aorta, and filled with parietal thrombi. The heart, apart from a concentric hypertrophy, showed nothing abnormal. The superior vena cava was compressed throughout its whole extent, its lumen being scarcely larger than a pen-holder, while the lower venous trunks were free. The trachea was eroded and nearly perforated.

Münchener medicin. Wochenschrift, Feb. 19 and 26, 1901.

A Curious Foreign Body in the Urethra.—O. Schulze was consulted by a patient presenting the inflamed meatus and copious purulent discharge of an acute gonorrhœa. A short distance behind the meatus, however, a hard foreign body could be felt which was removed with some difficulty by means of a polypus forceps. On inquiry it was found that the patient was suffering from a prostatic discharge which he had considered as seminal and had endeavored to check by an improvised stopcock to his urethra. Believing that if the flow were prevented from escaping externally all would be well, he had taken a piece of small rubber tubing four inches long, and inserted into one end a short piece of lead pencil which had been bored through. Into the hole in the lead pencil a plug was fitted and the whole affair pushed into the urethra, leaving only a little of the lead pencil protruding, so that after each urination the hole could be tightly plugged. The apparatus had been in successful operation for a number of weeks, when in putting the plug into place the apparatus had been pushed back out of reach and could not be brought out again. Considerable cicatricial contraction with stricture formation resulted from the ulceration the foreign body had produced before removal.

The Treatment of Fibrinous Pneumonia.—H. Pässler says that modern therapy does not command any new remedies of marked value, but that an exact and scientific treatment demands a careful analysis of the sources of danger and the early institution of appropriate remedial measures. The causes of death in this disease may be grouped as follows: (1) In many cases the fatal result is due to actual suffocation, owing either to unusual extension of the diseased areas or to inflammatory œdema, by which the available respiratory surface is reduced below the amount necessary to support life. (2) In rare instances the pressure in the right heart is raised to an insurmountable degree by the increased resistance of the pulmonary circulation. (3) Complications, of which chronic alcoholism with the risk of delirium tremens is very serious, while others depend on an already existing cardiac insufficiency due to myocarditis or poorly compensated valvular disease, arteriosclerosis, obesity, chronic nephritis, emphysema, kyphoscoliosis, and old age. (4) All of these, however, are less serious than the risk which always attends a severe pneumonic infection, that a state of pneumococcus sepsis will be set up, sufficiently intense to overwhelm the vasomotor centre.

Another Case of Intestinal Obstruction Treated with Atropine.—A. Dietrich adds another to the list of cases of intestinal obstruction in which operative intervention has been obviated by the use of atropine in large doses. His patient, a man aged twenty-five years, was suddenly taken with severe pain in the left iliac region, which did not yield to ordinary measures, and was accompanied by absolute constipation with absence of flatus. The condition steadily grew worse, until finally the typical picture of the disease, with fecal vomiting and collapse, was presented. Three atropine injections of gr. $\frac{1}{50}$, $\frac{1}{10}$, and $\frac{1}{20}$ respectively were given, in rapid succession, with the result that abundant flatus, soon after followed by a solid movement, was passed in a few hours. In view of the fact that all other treatment—opium, high irrigations, poultices, etc.—had proved ineffectual, and that the condition was rapidly becoming more serious when the atropine was given, the author does not hesitate to ascribe to this drug the whole credit for the cure. Slight toxic symptoms were noted, but did not cause much distress and soon disappeared.

Vagitus Uterinus.—Frankenstein adds a case of this rare occurrence to the literature. The patient had already had seven successive still-births, followed by one in which a live fœtus was extracted by version. Therefore, when the accoucheur was called again and found the labor progressing very slowly and the fœtal heart sounds growing weaker, he at once started to perform a podalic version. The hand was easily introduced into the uterus and the foot grasped when, just as traction was made, two distinct cries, heard and attested to by four different persons, were uttered by the fœtus. The author believes that a small amount of air entered the uterus together with his hand, and that this, combined with the reflex stimulation produced by the seizure of the foot, sufficed to excite a respiratory movement. The child was extracted without difficulty and survived.

The Malaria Parasites.—G. Maurer recognizes only three forms of the plasmodium, and gives the following rules for their differentiation: If only ring forms are found, the diagnosis of pernicious fever may be made, and if in addition crescents are present and a second examination a few hours later still shows nothing but these and rings, there is no room for any doubt. Quartan fever is indicated by large parasites, with or without rings, which leave the cell body intact. Granulation of the cell body, together with smaller size of the parasite, is evidence of tertiana. If no parasites are found in two specimens of blood taken at intervals of a few hours, malaria may be excluded. Fresh preparations may be used for diagnosis, but are less satisfactory than stained specimens, and require greater skill on the part of the observer.

The Modified Open Treatment after Operations on the Eyeball.—E. Heimann condemns the customary tight dressing applied after operative procedures on the eyeball as exercising an undesirable amount of pressure, impeding the natural cleansing movements of the eyelid, being easily displaced and insecure, promoting the stagnation of secretion and growth of bacteria, and causing the patient great discomfort and annoyance. The treatment he recommends consists in the application of some form of dressing so contrived as to relieve the eye itself from all pressure and to permit unrestricted motion of the lids. This may easily be constructed of wire, rubber, celluloid, etc., and will protect the wound against infection and mechanical injury, without being open to the objections urged above.

A Case of Gonorrhœal Endocarditis Furnishing Pure Culture of the Organism.—M. Wassermann reports a case which appears to settle the moot point as to whether the malignant endocarditis sometimes following gonorrhœal infection is directly due to the virus causing the original disease or represents a secondary pyæmic process. In this case the aortic valves were covered with fresh verrucous vegetations, from which organisms were obtained in pure culture, which by their tinctorial, cultural, and morphological characteristics were undoubtedly gonococci.

A Contribution to the Knowledge of Acute Sublimate Poisoning.—Paul Krause reports a case in which gr. xxx. of corrosive sublimate were taken with suicidal intent. After a protracted convalescence the patient recovered, apparently without permanent damage to any of his organs; indeed, a chronic pulmonary tuberculosis from which he had been suffering seems to have been brought to a temporary standstill. In addition to the usual symptoms attending acute bichloride poisoning, there developed stomatitis with secondary purulent parotitis, gastritis with hæmoptysis, enteritis and colitis with bloody stools, and severe nephritis. A peculiar manifestation was a rash gradually involving the whole body and resembling that sometimes observed in cholera cases.

The Treatment of Torticollis.—Joachimsthal believes that while the long-accepted theory of Stromeyer as to the causation of this deformity holds true in the majority of cases, still there are some in which other associated congenital deformities and the family history point to heredity as the most active etiological factor. Stromeyer's theory as modified by Mikulicz assumes that during labor a rupture of the sterno-mastoid occurs, and that a consequent invasion by bacteria produces a fibrous myositis which is followed by contraction and deformity. The treatment recommended consists in open division of the contracted soft parts.

On Non-Obstructive, Post-Operative Anuria.—By F. T. Brown. The histories of two cases are given in detail. In the first case a boy aged nineteen years was operated upon for pyonephrotic kidney. He died four days later, having had a failing heart and renal suppression. The author thinks that the latter may have been due to either (1) chloroform anæsthesia, (2) compression of the kidney and vessels of its pedicle against the spine when the superimposed body rested for a long time on sand-bags, leading to a subsequent hyperæmia, (3) some essential vasomotor reflex started by ganglionic pressure or through the renal plexus, from the removal of the fellow kidney, or by a congestion incidental to an increased physiological demand. Subsequent to the operation, he suspects that a weak heart favored a condition of comparative stasis (passive congestion). If this last is the correct explanation of the congestion, and if the lowered heart pressure at the same time could so quickly bring about suppression, then this anuria had but the remotest, if any, influence in causing death. The author reviews the different steps of his operation, and is inclined to think that under similar circumstances he would induce anæsthesia with nitrous oxide gas and continue it with ether, would be careful to expose the operative field with the least possible pressure upon the healthy kidney, and would use hot lavage for vomiting. He thinks that the first manifestations of anuria would be looked upon, when the pulse was small and rather rapid, as due to a vasomotor paresis—in other words, cardiac weakness with consequently lowered renal pressure, the result of shock—and the complex condition would be energetically combated with the most approved methods of stimulation.

Eversion of the Tunica Vaginalis as a Remedy for Hydrocele.—By Dudley Tait. The author commends Longuet's operation, which consists essentially in the inversion of the cellulo-vaginal layers, without decortication or hæmos-

tasis and is thus described: Under local anæsthesia a transverse fold is taken up over the testis and cut with the scissors down to the serosa, which is immediately taken up and cut in a like manner. Neither the superficial nor the deep cut should exceed 3.5 cm. The testicle is then drawn out, upward and forward, as much as possible, the scrotum being at the same time pulled in the opposite direction by the assistant. The tunica vaginalis and overlying fibrocellular tissues follow and are turned inside out. One or two sutures are taken to secure the vaginalis in its new position; these stitches are placed in such a manner as to avoid injury or strangulation of the cord. Chromic catgut (two weeks) is perhaps preferable to the ordinary gut, which is absorbed too early. The testis is not replaced in its original position, but a new bed is made for it in the middle of the inner lip of the incision, by gently dissecting the cellular tissue with the finger. The resulting new cavity is inside of, and parallel to, the old cavity. The testicle is slightly twisted on its axis, not being in normal anteversion but in retroversion rotated inward a quarter of a circle and lying directly against the raphe. The position of the testicle may be defined as retro-latero-version. The wound in then closed with two or three stitches. The operation is completed within a minute or two; no hemorrhage is noted, and the immediate effects are barely noticeable, thereby differing radically from all the other methods. There are no local reaction or infiltration of the soft parts and no tenderness, and within a few hours after the operation palpation of the testis does not elicit more than the normal sensitiveness.

Hernia of the Fallopian Tube without Hernia of the Ovary.—By P. F. Morf. The explanation of the condition found on opening the abdomen would appear, according to the author, to be the following: The patient had a congenital hernia of the left oviduct, complicated by an epiplocele, the fat of which underwent serous change. Shortly before the hernia became irreducible, the patient acquired an acute vaginitis, the infection extending upward along the genital tract into the hernial sac. The invading microorganisms finding a favorable culture medium in the mucoid substance of the omentum, multiplied, exudation and pus formation occurred, and as a result the hernial tumor increased in size and became irreducible. There are several reasons why hernias of the tube without the ovary are rare: (1) When the tube is found in a hernial sac, it is usually there because it has followed a hernia of the ovary. (2) The tube is so deeply placed in the pelvis that exceptional circumstances are necessary to force it into the hernial openings. Its relation to femoral and inguinal openings is such that, under ordinary conditions, increased intra-abdominal pressure—such an important factor in hernias of other organs—tends to force it more deeply into the pelvis rather than toward these openings. (3) When hernia of the tube has developed, the ovary, from its intimate relation to the tube, is also soon drawn into the sac. This seems probable from the fact that in a number of the appended cases the ovary was found close to, or just at, the hernial opening through which the tube had already passed.

Contribution to the Surgery of Malignant Disease of the Prostate Gland and of the Tonsils.—By N. Jacobson. A case is reported of primary carcinoma of the prostate, occurring in a man aged sixty-one years. His recovery from the operation was fairly good, but the patient died five months later from hemorrhage into the bladder. A study is made of the literature of the disease including a résumé of reported cases. The author also reports a case of primary sarcoma of the tonsil and one of epithelioma of the same organ. The sarcoma occurred in a man aged thirty-one years, and was removed by operation from without, but its extreme size rendered necessary the section of the lower jaw. The epithelioma occurred in a man aged sixty-one years, and was removed with the galvano-cautery snare, under cocaine. The patient is now living and healthy (operation in 1889). An analysis is made of ninety-five cases of malignant disease of the tonsils, references being made to the original channels of publication.

Report of a Case of Recovery after Abdominal Section for Multiple Gun-Shot Wounds of the Abdomen.—By F. Martin. The injuries received consisted of perforations of the liver, gall bladder, hepatic flexure of the colon, two perforations of the small intestines, and one of the rectum (deep in the pelvis), with active and excessive hemorrhage. The author considers the case one of special interest, (1) because of the wide area involved in the damage done, (2) because of the lapse of time between the injury and operation (almost a full day and, in addition, a long railroad journey, with hemorrhage going on within the abdomen), and yet recovery ensued, and (3) the wide extent of the opening of the abdomen made necessary by the widely distributed areas of damage.

Periosteal Osteo-Sarcoma of Upper Extremity of Femur; Ligation of Common Iliac Artery with Amputation at Hip-Joint and Removal of a Portion of Pelvis; etc.; Recovery with Freedom from Recurrence at End of Nearly Sixteen Months.—By L. Freeman.

Resection of the Pendulous Fat Abdominal Wall in Cases of Extreme Obesity.—By L. Peters.

Diagnosis of Stone in the Kidney by the X-Ray and its Treatment.—By A. D. Bevan.

The Edinburgh Medical Journal, March, 1901.

Psychoses Following Pelvi-Abdominal Operations.—J. Halliday Croom records a number of cases of mental disturbances occurring after operations which were uncomplicated *per se* and simple, when the operation was entirely successful, and all in women who, as far as could be traced, had no hereditary tendency whatever in that direction. The author thinks it remarkable that it has not been shown that insanity is more common after operations on the genital organs than after operations on any other organs. When one recognizes the frequency with which mental troubles are apparently associated with the normal occurrence of changes such as puberty, menstruation, pregnancy, and the menopause, it may be considered almost remarkable that women escape from these disorders as easily as they do.

On the Prognosis of Acute Disease.—R. Hingston Fox considers benign and malignant acute diseases, inheritance, past history, present condition of the patient, general physique and habits, nervous system and temperament, and the condition of the circulatory, respiratory and digestive organs, skin and kidneys. The first art we acquire, he says, is to treat disease. To treat the patient is a talent which comes later. But the personality of the sufferer, his idiosyncrasy, his equation, enter largely into prognosis. It is by degrees that we learn the value of rest—not "doing nothing," but "not hindering" anything—and learn to trust the human body. As Dr. Sutton said, "Doctors who look too much on morbid anatomy, the dead side of disease, are apt to give too gloomy prognosis. They cannot trust the human body."

Some Recent Researches on Alcohol; their Bearing on Treatment.—J. Mackie White gives a *résumé* of recent scientific work on the action of alcohol as a stimulant, as to its effect on the tissues of the body, in diseases of the nervous system, alimentary diseases, kidney affections, septic cases, pneumonia, and alcoholic subjects. His conclusion is that we should clear our minds of prejudices regarding the stimulating and sustaining virtues of alcohol and substitute for them more accurate ideas. When we prescribe alcohol, he says, let us endeavor, in the light of the most recent scientific knowledge, to exercise at least as much thoughtful care in regard to our patient's welfare, as when we order any other powerful drug, as arsenic, morphine, or strychnine.

Journal of Tropical Medicine, Feb. 15 and March 1, 1901.

Pani Ghao.—Osborne Browne having read an article in the December number of this journal on "Pani Ghao, or Sore Foot of Assam," states that it appears to him to be the same disease as that known as "ground itch" in British Honduras, but presenting a worse form. The disease occurs in people who walk in mud, and is therefore commonest in wet seasons. It begins as an intense itching about the toes and between them, and sometimes on the sole or dorsum of the foot. This itching is most intense at night in bed. Then the toes and foot get swollen and red, and vesicles, preceded by papules, form, and much clear serum exudes from them. The condition lasts about a week. The treatment employed by the natives is to apply hot green plantain skins, or hot cloths; in fact, anything hot soothes the itching. Hot lotions are very grateful.

The Royal Army Medical Corps—the Regimental System.—An anonymous writer discusses the reasons for the unpopularity of the Royal Army Medical Corps among the young graduates of the Medical School. He considers that it dates back to the day when the regimental surgeon was abolished and the present station-hospital system established. The doctor ought to live in the regimental lines to treat and keep in health a body of men like a regiment. Every battalion of infantry and every regiment of cavalry should have at least two medical officers, and every battery one. Every regiment should have its small detention

hospital; every station hospital should have a large and completely equipped laboratory, and doctors should be allowed to employ soldier clerks.

Ophthalmic Notes from the Tropics.—H. Campbell Highet gives a list of the eye diseases most frequently seen in Singapore and Bangkok. Syphilitic diseases of the eye show some peculiar features; syphilitic iritis appears to be a much more severe disease in the tropics than in temperate climates. The results of specific treatment of tertiary lesions of the eye are as a rule very satisfactory. The proportion of malarial affections of the eye is 2.2 per cent., and cases seen consist of œdema of the ocular and palpebral conjunctiva, corneitis, interstitial keratitis, cortical cataract, retinal hemorrhage, and night blindness. In cases of leprosy the eye lesions are not marked in the anæsthetic form, but are severe in the tubercular form.

Water-Itch, or Sore Feet of Coolies.—A. B. Dalgetty fully describes this disease. He has found in the vesicles the ova of an acarus, whose life history and anatomy he gives in detail. The disease affects chiefly those coolies who are in a weak state of health; anæmia is very common in tea gardens, especially among the women, and it is these latter who suffer most severely. As to treatment the application of a strong solution of lime and sulphur is a good means of cutting short the malady. The value of wearing shoes as a preventive measure has been completely proved. Coal tar is good as a preventive and as a curative agent.

Craw-Craw.—R. A. Bennett reports a number of cases. The name craw-craw is given by the ordinary uneducated native of Old Calabar to practically all skin diseases; the more intelligent native divides it into three classes, leprosy or bad craw-craw, tinea circinata or Kroo boys' craw-craw, and craw-craw proper. The author suggests that craw-craw as a specific name should be abandoned, and that the disease should be included in the class to which he believes it belongs, viz., pustular eczema.

Pinta.—P. G. Edgar reports the case of a woman in Perak, which is of interest as demonstrating the existence of the disease in the Old World. It had been supposed to exist only in the New World, especially in Central America and Mexico. In addition, interest attaches to the fact that a very large extent of cutaneous surface was involved, and that the disease extended into the palms.

Case of Acute Catarrhal Dysentery, with Complications of Synovitis of Knee.—N. G. Ross reports a case which he considers to be an example of a class of cases to which Brault and others have recently called attention; namely, those in which arthritis is a complication or sequela of dysentery.

The Montreal Medical Journal, January, 1901.

Typhoid Fever.—H. A. Lafleur describes a case in which the signs pointed to a probable perforation of the bowel. An operation was performed, but when the peritoneum was opened no fluid or gas escaped, and the surface of the bowel seemed normal. Thickenings in the course of the lower part of the ileum, due to the typhoid ulcers, were distinctly felt, but no perforation could be found, or even any sign of local peritonitis. In the angle formed by the junction of ileum and cæcum there were two very red lymph glands, swollen, it seemed, almost to the point of rupture, and standing out prominently from their peritoneal investment. Two quarts of warm, decinormal saline solution were introduced into the peritoneal cavity, and the abdominal wound was closed. The patient made a good recovery.

Typhoid Fever Operated on for Perforative Peritonitis, with Negative Finding.—N. F. Hamilton reports a case in which operation was indicated, as a perforation was believed to have taken place. An examination of the blood showed 14,000 leucocytes. Some clear, reddish-colored fluid was found free in the abdomen. No inflammatory lymph was seen. The vessels in the visceral peritoneum were turgid, and several mesenteric glands were enlarged and deeply congested. There was no evidence of perforation. The patient made an uneventful recovery.

The Scottish Medical and Surgical Journal, March, 1901.

Gastric Hemorrhage and its Surgical Treatment.—A. W. Mayo Robson holds that all cases of acute uncomplicated gastric ulcer should be submitted to long-continued and thorough medical treatment; should the ulceration persist, or relapses occur, gastro-enterostomy should be performed to secure physiological rest and relieve the hyperacidity of the gastric juice. Perforation demands immediate surgical treatment. Disabling adhesions around the stomach and pylorus, pyloric contraction and hour-glass contraction due to chronic ulcers, leading to pain, dilatation, loss of flesh, and general impairment of health, now often treated as chronic indigestion, should be treated surgically. In recurring hæmatemesis from gastric ulcer, surgical treatment is decidedly called for. In acute hæmatemesis the co-operation of physician and surgeon is advisable, so that if relief is not obtained by medical and general treatment, surgical means may be adopted if the bleeding is believed to occur from a large vessel.

A Case of Acute Cellulitis Treated by Antistreptococcic Serum.—Francis Kelly had a patient suffering from cellulitis of the right hand. Incision and evacuation of the fluid gave temporary relief, but the swelling returned, rapidly extending up the arm, while the temperature rose to 104°. Under chloroform the hand and arm were freely incised and drained. Streptococci were found in the seropurulent discharge. Ten cubic centimetres of antistreptococcic serum were hypodermically injected, and on the following day two additional injections were given. The temperature fell, the swelling was reduced, and the patient made a good recovery. The author attributes the good results to the serum.

Ether as an Anæsthetic.—Thomas D. Luke pleads for the use of ether instead of chloroform as an anæsthetic in general surgery. He combats the objections urged against ether, and quotes in support of its use the conclusions reached by *The Lancet* and Hyderabad Commission's Report.

The Edinburgh Hospital in South Africa and its Work.—By Francis D. Boyd.

Ear, Nose, and Throat Journals.

Tumor of the Thymus Cured by Thyroid Extract.—C. Miot records the case of a child of five years presenting just at the sternal fourchette a tumor the size of a large cherry, apparently extending below into the mediastinal space, where it was fixed by a pedicle. It had a hard feel, and the skin over it was freely movable. It did not move during deglutition, and was considered to be an enlarged thymus, formed of two lobes with a sort of connecting isthmus. The child was anæmic, and suffered from frequent febrile movements and disturbed sleep. The mother stated that the growth had appeared in the course of a single night, after the child had been in the country and had played and shouted considerably. Miot conjectured that, considering the vascular condition of the thymus at this age, there might have been a congestion of the gland and a hemorrhage into its substance. The application of the electric current and the administration of an iodide were without effect, and it was decided to try thyroid extract. Under a dosage of 10 cgm., continued with intermissions for over a period of four months, and gradually increasing to three times the quantity named, the tumor entirely disappeared and the general condition of the patient was greatly benefited.—*Rev. hebd. de Laryngologie*, January 26, 1901.

Indications for Intralaryngeal Operations in Cancer of the Larynx.—Gougenheim and Lombard quote as the conventional justification for the intralaryngeal method the existence of cases in which certain forms of intrinsic cancer remain for a long time limited to one cord or one ventricular band, and do not tend to progress. This condition obtains in patients of advanced age, just that class in which we feel reluctant to operate by the usual methods. The slow growth has an undoubted relation to the exact nature of the neoplasm, for certain epitheliomata and sarcomata with a predominance of the fibrous element tend to grow very slowly. Moreover, there are pedunculated epitheliomata in which immediate removal may be required to anticipate certain accidents. The authors do not believe, however, that the foregoing justifications are logical in the great majority of cases, nor that the natural channels can ever serve as a universally available avenue for removal of malignant deposits in the larynx. Intralaryngeal removal should be regarded rather as an operation for diagnostic purposes than for cure.—*Annales des Maladies de l'Oreille*, etc., January, 1901.

Giorn. Internazion. delle Scienze Mediche, Jan. 31, 1901.

The Supposed Defensive Power of the Phagocytes of the Lymphatic Glands against the Syphilitic Virus.—Tommaso de Amicis holds that modern experimental research has in nowise destroyed the semiological value attributed by clinical observation to the lymphatic ganglional system in relation to syphilis. Hence, when the physician has a case of syphilis to treat, he should not congratulate himself that the glands are notably and extensively swollen, trusting to their phagocytic power, but should resort to every therapeutic measure known to science to avert the possible and serious consequences which may result from the gravity of the infective process.

The Localization of Koch's Bacillus in the Isthmus of the Fauces and in the Tonsils.—Domenico Tanturri concludes that the primary latent tonsillar tuberculosis of Dieulafoy is not materially demonstrable. Secondary tuberculous infection of the tonsils from adjacent parts, although not common, can be demonstrated. This affection is characterized by the presence of numerous tubercles, or, more rarely, by a simple infiltration.

Clinical Department.

HERNIA OF THE ADDUCTOR LONGUS MUSCLE, WITH OPERATION.

By CLARENCE A. McWILLIAMS, A.M., M.D.,

ASSISTANT SURGEON TO THE PRESBYTERIAN AND TRINITY HOSPITALS, NEW YORK.

The following cases will be interesting as illustrating a rather rare condition. An Irishman presented himself at the Presbyterian Hospital dispensary on February 26, 1900, complaining of the presence of a swelling on the inner and upper aspect of the front of his

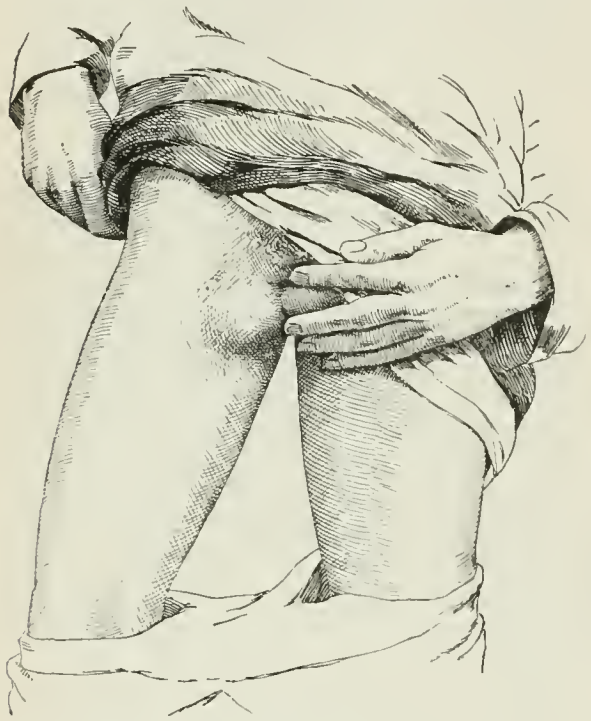

Fig. 1.

right thigh. He gave the following history: In November, 1899, while playing a game of "Irish bowling" he suddenly felt a sharp pain in the upper part of the right thigh in the same position as the subsequent swelling. This was not sufficiently severe, however, to prevent his continuing to play the game. That evening the upper and inner region of the right thigh became sore and tender. The next day a bluish discoloration about the size of a silver dollar appeared under the skin, below and internal to the right saphenous opening. The soreness and discoloration remained for about a week and then disappeared. He was not during this time incapacitated from walking. Two weeks after the original pain, he noticed for the first time a small swelling at the site of the previous discoloration, which was slightly tender, but this soon passed. This swelling gradually increased in extent, till at the end of a month it was about the size of a lemon, and it has remained of this size since then. The man comes for treatment, complaining of the annoyance the tumor caused by rubbing against his clothes and against the opposite thigh.

On examination a swelling was found on the front of the upper and inner aspect of the right thigh, about three inches below Poupart's ligament; it was about three inches long and in transverse extent two inches wide, oval in shape. The skin over the tumor was normal in appearance and was freely movable. The tumor was not tender, but was soft, semi-fluctuating; its surface was smooth, and it was attached to the deeper parts. The limits of the tumor were sharply defined from the adjacent structures. It was not lobulated and was of the same consistency throughout. There was no expansile impulse on coughing, and it was flat to percussion. There was no pulsation visible nor aneurismal bruit to be heard. The swelling became much more prominent and harder when the effort was made to inward rotate and adduct the thigh when this was in the abducted and rotated outward position, the knee being flexed. Several considerations at once suggested themselves to explain the tumor, namely, a lipoma, an adenitis, a large varicose vein, obturator or femoral hernia, psoas abscess, an aneurism, or a muscle hernia. The latter was accepted as the true condition. On this supposition the symptoms were explained as follows: The original pain was due to the splitting of the muscular sheath and the fascia lata over the muscle, which caused a certain amount of ecchymosis. The muscle eventually pushed itself through the fascial split and caused the present swelling. It was found impossible by any means to reduce the size of the swelling, and operation was advised and consented to. Ether was administered, and after the usual antiseptic precautions an incision was made almost vertically over the tumor. After division of the deep layer of the superficial fascia, a muscular mass was immediately come upon. The adjacent tissues were separated entirely away from both sides of the tumor which was thought to be the adductor longus muscle. An endeavor was made to isolate the edges of the split fascia lata, with the purpose of bringing these edges together and suturing them over the muscle, thus closing the rent through which the muscle protruded. This proved not to be feasible, however, as the fascia was found to be too thin, and too contracted to allow of its being drawn over the mass with any certainty of the stitches not cutting through the fascia. It was then deemed best to excise the muscle, which was separated from the adjacent tissues. Ligatures of catgut were then thrown about the musculo-tendinous

Fig. 2.

origin and insertion of the muscle to prevent the ends of these from bleeding, and the muscle between these ligatures was excised. The thin fascial edges were then sutured together with catgut, and the skin wound was closed. A plaster-of-Paris spica was applied over the dressing to immobilize the hip joint. The subsequent

history was uneventful. The wound healed kindly, and after ten days the plaster splint was removed, and the man resumed his work. He now tells me that his right limb is as strong as ever. Examination shows no evidence of any swelling at the site of the scar. The man plays the game of bowling as well as ever. On inquiry he told me that two of his friends have similar swellings produced by the same game. One of these men I examined. His was an identically similar swelling in the same situation and on the right thigh. He had had the swelling for three years, but suffered no discomfort whatsoever from it. The history of its appearance was just like that of the first patient: while playing the game of bowls, sudden pain in the thigh, followed by the gradual appearance of a tumor in the course of time. In this case no operative procedure was advised, as no discomfort was caused by the tumor.

The etiology of these herniæ is interesting. The game of "bowls," which produced them, consists in running at a high rate of speed, when a sudden skip is made by powerfully adducting the right leg toward the left, and at the same time by an underhand swing of the right arm an iron ball twenty-eight ounces in weight is thrown as far as possible. The adductors of the thigh are thrown suddenly and violently into strong contraction. A probable sudden overaction of the adductor longus in these cases split the sheath of the muscles and the fascia lata, and the herniæ followed. It is possible that had an elastic girdle with a pad been applied immediately after the onset of the pain, the subsequent herniæ might have been prevented, or the same result would have been produced by suturing the split in the fascia immediately after the accident. When the hernia of the muscle has once occurred, excision of the muscular belly is the only curative procedure. In cases of wounds of the thigh, the divided edges of the fascia should be sutured together to prevent a subsequent muscle hernia. Muscle herniæ affect most frequently the rectus muscles of the abdomen and the muscles of the thigh, particularly the adductors. The latter occur especially among cavalry and artillery soldiers. A case of hernia of the semi-membranosus has been reported, also one of the biceps femoris. Giess was the first who sought to cure muscle herniæ by operation.

The illustrations are taken from two cases, the tumors of which were exactly similar and in the same position. One shows well the tumor in one of the cases before operation. The other picture shows the good result in a different case after operation. The wound healed per primam, and there is no swelling perceptible.

ICHTHYOL IN THE TREATMENT OF DEEP-SEATED INFLAMMATIONS.

By WALTER T. SLEVIN, M.D.,

BROOKLYN, N. Y.

After having used ichthyol in a number of different formulæ, the resultant action of which has not been as desired, I have at last obtained a formula which, if used properly, will relieve deep-seated as well as superficial inflammations. The formula is as follows:

℞ Ichthyoli..... gr. xlv.
Plumbi iodidi..... gr. xlv.
Ammonii chloridi..... gr. x.
Vaselini.....q. s. ad ʒi.
M. ft. ungt. S. As directed.

It should be applied by rubbing upon the inflamed parts. The results of the application in three different cases are here described.

Case I.—James F——, aged twenty-one years, had a marked swelling on both sides of the face, involving the nose and extending to the eyes, with high fever, great prostration, and partial delirium.

Diagnosis: Erysipelas.

Treatment: The patient had the preparation rubbed into the site of the inflammation every hour; subsidence of the condition in twenty-four hours.

Case II.—Mary McN——, aged thirty years, had a large swelling on the left side of the face, involving the glands of the face and neck; she could not open the mouth; had high fever, dyspnœa, dysphagia, and presented the appearance of impending death. The swelling was very hard and tense; therefore to incise it would have been futile.

Diagnosis: Peritonsillar abscess (quinsy sore throat).

Treatment: Application of the preparation every hour, with cure in twelve hours.

Case III.—John C——, aged six months, had râles over both sides of the chest, bronchial breathing, bronchophony, and slight dyspnœa.

Diagnosis: Broncho-pneumonia.

Treatment: The preparation was rubbed into the chest, with disappearance of all symptoms on the following day.

From the cases described, it can be readily seen that in acute inflammatory conditions the results have been most excellent.

It seems to me that this formula should be most effective when used in chronic conditions, inflammations, glandular enlargements, and ulcerations, whether of specific nature or otherwise, as it is a great aid to absorption.

I hope that this formula will be made use of by the profession and its effects reported.

N. B. The substitution of glycerin, oleum theobromæ, or unguentum aquæ rosæ for vaseline is more suitable to some cases.

386 Union Street.

A CASE OF FATAL STENOSIS OF THE LARYNX FOLLOWING INTUBATION FOR PAPILLOMA.

By F. L. WACHENHEIM, M.D.,

ATTENDING PHYSICIAN, CHILDREN'S DEPARTMENT, MOUNT SINAI HOSPITAL DISPENSARY, NEW YORK.

Joseph V——, aged two years, was seen by me for the first time on June 26, 1900, suffering from typical but moderate laryngeal dyspnœa, without any other local or general symptoms. The following history was obtained.

The patient had been suffering from similar dyspnœa for more than a year. The only active treatment resorted to had been intubation. This had been tried during the previous winter for a space of several weeks, with no apparent result except to increase the child's distress. I could not learn whether the true condition had been diagnosticated at that time.

As a general physical examination of the other viscera proved absolutely negative, I made a provisional diagnosis of papilloma of the larynx. A laryngoscopic examination was rendered impossible by extreme distortion and folding of the epiglottis, although the child was not especially refractory.

As the condition of the patient did not just then seem urgent, the parents were requested to bring the child again in three days. True to human nature, they brought him in a week. By that time the dyspnœa had assumed quite a serious aspect, and immediate application for hospital treatment was advised, with a view to the possible eventual need of a hasty tracheotomy. The parents decided to wait three days more, but the child died rather suddenly in forty-eight hours, apparently from strangulation.

Twelve hours after death an autopsy was made, which was only partial, owing to the religious scruples of the parents. The larynx and trachea were, however, secured entire, and presented the following condition.

The lumen of the larynx was exceedingly constricted, barely admitting a probe; the epiglottis was folded

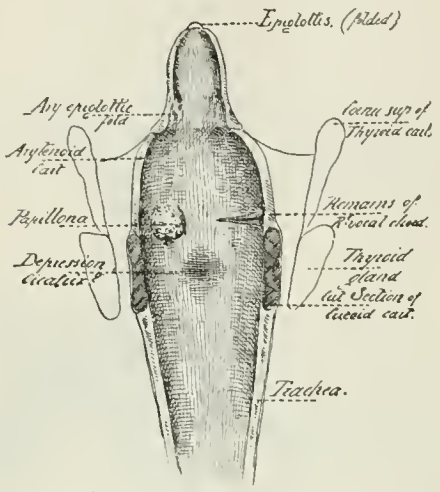

Fig. 1.—Section in Median Line.

tightly and drawn backward. The mucous membrane in general was apparently thinned and anæmic, especially over the anterior surface, without any local redness. The right vocal cord was represented by a small uneven nodule, the left cord was largely replaced by a warty friable mass of about the size of a very small pea. There were cicatricial depressions below the arytenoids. The ventricles and false bands were quite obliterated. In spite of the almost total disappearance of the cords themselves, the glottis was practically closed by the general constriction of the surrounding parts and the very moderate-sized tumor. The trachea was entirely free from pathological changes; the thyroid body was of normal size. (See Fig. 1.)

The apparent extensive destruction of the vocal cords, the evidently cicatricial narrowing of the upper larynx, and the extremely friable nature of the small mass made one naturally consider for a moment the possibility of an exceedingly atypical case of laryngeal tuberculosis. It is, however, very unusual to have the posterior commissure free in tuberculosis of the larynx, and besides, this disease is excessively rare in young children. Spreads of the friable matter showed only epithelial cells; tubercle tissue, granulation tissue, and bacilli being entirely absent.

Sections through the whole left vocal-cord region showed the cord very markedly shortened and somewhat thickened, its connective tissue largely infiltrated with round cells, the elastic tissue diminished, the fibrous tissue increased. The epithelium on the upper surface showed no tendency to invade the deeper tissues, but was itself hypertrophied. The papillary layer was flattened out. From the upper surface projected large papillæ up to 1½ mm. in length, very friable and often broken off. The papillary layer and epithelium seemed about equally affected, as is characteristic of this class of tumors. (See Fig. 2.)

The case, more closely studied, presents some curious and perhaps unique features. The shortening of the cords is evidently not so much if at all due to direct local traumatism, as to the general contraction (cicatrization) of the larynx; this view being corroborated by the disappearance of the false bands and ventricles, and the great deformity of the epiglottis. We naturally assume that the intubation must have been responsible for these changes; papilloma in general and this one in particular being so conspicuously a benign growth as not in any way to account for the atrophy and distortion of the laryngeal tissues. The question arises, how the operation can be blamed for this unfortunate condition, and is best answered by a brief *résumé* of the history of intubation in chronic stenosis and more especially in papilloma, and the pros and cons of this therapeutic procedure.

First, let us review the history of intubation in chronic stenosis of the larynx. Loiseau[1] was the first to suggest intubation of the larynx, Bouchut[1] the first to employ it, both originally with reference to relieving acute pseudo-membranous stenosis, for which purpose the dictum of Trousseau and the Imperial Academy[2] consigned it to early but not permanent oblivion.

For the treatment of chronic stricture, the tube was taken up again by Schrötter,[3] who employed graduated hard-rubber catheters. These instruments had two serious faults: their shape was in no way adapted to the rima glottidis, and they could not be left *in situ* on account of their liability to slip.

Almost thirty years after Bouchut, O'Dwyer's great invention appeared on the scene, and one of the early applications of his tubes was in a case of cicatricial stenosis.[4] In a paper read before the Ninth International Medical Congress[5] he presented four additional cases. Stoerk[6] was the first in Europe to apply O'Dwyer's instrument to this class of cases, but does not at that time seem to have fully realized that great superiority to Schrötter's tubes, which lies just in avoiding the two great defects of the latter. Since then, O'Dwyer's method has rapidly become the regular procedure in cicatricial stricture of the larynx.

Proceeding to the subject of obstruction by tumors, in particular papilloma, it undoubtedly seems at first glance a short step to extend the range of intubation from cicatricial stricture to this field. The first report I can find, recommending intubation for papilloma of the larynx, consists of two cases narrated rather enthusiastically by Baldwin,[8] in which the treatment effected apparent cure. Schmiegelow[9] gives the case of a child aged three years, in which the stenosis was relieved, but laryngotomy had finally to be performed. He considers intubation dangerous in papilloma. Albert Rosenberg[10] also warmly recommends intubation, but only in those cases which are not readily

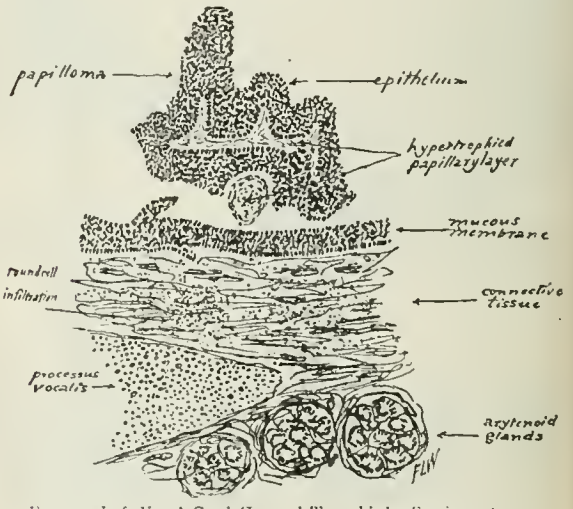

Fig. 2.—Left Vocal Cord (Lateral Two-thirds) Section × 50.

operable from above, in which the growths are multiple, or in which the dyspnœa is urgent. He has since somewhat modified this standpoint, but not in favor of the procedure.

There is, however, another side to the picture. I have mentioned Schmiegelow's hesitancy to employ this treatment, but Lennox Browne[11] and Baumgarten[12] go farther: suggesting the possibility of breaking off

tumor fragments—recalling the extreme friability of the present specimen—with the dangers of serious hemorrhage and of foreign-body inhalation. I might add that it is generally agreed that intubation in these cases is, after all, a makeshift. Even if the forcible introduction and the subsequent pressure of the tube do break off bits of the tumor, and these are happily coughed up, I doubt if a permanent cure can thus be effected. Subsequent radical removal will be required, which, as my laryngological friends know, is not the easiest or most permanent thing in the world. Why not perform tracheotomy at once, and then operate on the tumor or tumors at leisure?

A more serious and probably more frequently incurred danger of the operation is that of injuring the laryngeal tissues. The usual total duration of the tube *in situ* in pseudo-membranous stenosis is forty-eight to ninety-six hours, though Seward[13] had a record of 1,128, and Baer[14] of 1,248 hours. From the earliest days of the operation gentleness of manipulation, frequent changing, and the shortest possible employment have been counselled.

Galatti[15] narrates two cases of his own, both of diphtheria, in which the tube was left in two hundred and thirteen and four hundred and thirty-six hours respectively, with consequent extensive decubitus. Previous to this, a case by Carr[16] and one by Schwalbe[17] are the two earliest I could find. Since then the subject has been gone into thoroughly by Baudran[18] and Fischer.[19] The authorities agree that the usual sites of laryngeal ulcers after intubation are on the anterior wall of the cricoid and below the base of the arytenoid, places against which the tube rests when in position; they also agree as to the dangerous strictures of the organ caused by cicatrization of these ulcers. I shall pass very briefly over the direct injury of the vocal cords by operators who are rough in their manipulations, or employ tubes of too great diameter; this class of cases merely going to show that intubation is not the trivial and easy procedure that one might imagine it to be at first sight.

In the face of this evidence we must decide the case against intubation, and, moreover, assume that the correct diagnosis was not made last winter, though an able clinician was in charge. Still, one might imagine that the task must have been less difficult than I found it, as the epiglottis could at that time hardly have been so great an obstruction to the view. We may pass over this point, as very few practitioners can perform laryngoscopy on a child of eighteen months, no matter how tractable. What is quite inexplicable, in the light of past experience, is that the intubation was so long persisted in, and so much valuable time for other more thorough procedures wasted.

After the above criticism, let us finally summarize what three of the best authorities, Baumgarten,[11] A. Rosenberg,[20] and Hunter Mackenzie,[21] substantially agree in considering the proper treatment of papilloma of the larynx. Three operations are recommended, to be chosen in the following order: First, the removal from above by curettage or cautery; secondly, tracheotomy with subsequent removal from above or below; thirdly, thyrotomy and anterior removal, with or without preliminary tracheotomy.

The first method is suitable for adults or older children, when the symptoms are not urgent. I cannot see how it is to be carried out in a child of two years, even if unusually tractable, which is never saying a great deal. The second operation is generally the appropriate one, when the first is not feasible; the third is universally recognized to be dangerous—a last resort. Intubation is scarcely mentioned, and then unfavorably; as before stated, it can never be more than palliative, and, as we have seen, is replete with danger.

It seems to me no supererogation to draw the following lessons from the case as presented:

1. Intubation is not to be employed indiscriminately whenever there is a laryngeal stenosis; tracheotomy is not yet obsolete.

2. In chronic laryngeal stenosis in children we must bear in mind the frequency of papilloma.

3. Prolonged intubation is always perilous, with special risks in cases of obstruction by tumors.

SOME FACTS BEARING UPON THE MALARIAL PROBLEM.

By RICHARD WAGGENER, M.D.,

INDIAN HEAD, MD.,

PHARMACIST, UNITED STATES NAVY.

So much has been written of late relative to the cause of malaria—there being such a wide-spread interest among scientific and professional men concerning the same—and, as it is a subject bearing upon the life, health, and prosperity of a vast number of people, I feel called upon to offer for publication my observations in this line during the past twelve years.

After graduating in medicine and upon locating in the town of Warrington, Fla., I immediately began, conjointly with the military surgeons on duty in the vicinity at the time, Dr. John W. Ross of the navy, and Dr. W. C. Gorgas of the army, a crusade against the drinking of pump (driven-well) water by the inhabitants. People were told, whenever the opportunity occurred, of the danger of drinking water obtained from their driven wells, and encouraged to get water for drinking-purposes from the large brick cisterns in the navy yard, and from the hospital spring, which spring furnishes the only water free from vegetable organic matter I have ever seen obtained from the ground in that locality.

There was some improvement in the healthfulness of the villages during the year 1892, yet malarial diseases continued to prevail. The task of convincing the residents that the water which they had been drinking for years was dangerous and unfit for that purpose was not an easy one by any means; but the work was persevered in, with the result that, in 1893, there was a still greater improvement in the healthfulness of the villages. From that time onward the place grew more and more healthful each year, and from the year 1895 to the time of my departure thence, September 28, 1900, I do not remember to have heard of, or to have been

called to, a single case of malarial fever, although nearly all of the medical work of the villages fell to my hands.

The most striking examples of the beneficial effect of the change of water, as well as the instances most clearly illustrating the correctness of the writer's views regarding the causation of malaria, occurred in large families—families which had not gone through a summer or autumn for years without having more or less malarial fever among the members, often two or three of them being sick at one time.

As to mosquitos, I am free to confess that I do not know whether the anopheles species exist in that locality or not, or whether they existed during the time when the locality was so notoriously malarious, and have since become exterminated through some unknown agency; but I do know that there are, and always have been, mosquitos there galore, apparently all kinds, big and little, brown and gray, and that they exist the whole year round. There is only one house in the village provided with screen doors and windows, and a large majority of the inhabitants sleep without mosquito nets.

As to the experiments now going on in Italy, I do not think that a few months' trial will demonstrate anything, should the evidence remain negative, because experience has shown that in the malarious sections of our South newcomers usually remain exempt the first year of their residence and develop malaria during the second or third year.

In conclusion, I will say that my observations have thoroughly demonstrated to my mind that malarial fevers are mainly, if not entirely, due to drinking-water contaminated with vegetable organic matter.

TETANUS.

By JOHN W. S. McCULLOUGH, M.D.,

ALLISTON, ONT.

The patient, a man fifty-six years of age, had his right foot crushed in a machine late in the evening of October 22, 1900. The two smaller toes were badly crushed, all of the soft tissues were torn from the heel, remaining attached, however, on the inner surface. The inside of the leg for a distance of three or four inches was chewed by the cogs of a pinion. There was severe hemorrhage. I saw him a couple of hours after the accident and, assisted by the local druggist who administered chloroform, I removed the crushed toes and the metatarsal bone of the little toe, scrubbed the foot and wounded parts with soap and water and with bichloride solution 1 : 1,000, adjusted the torn flap, and applied a moist dressing of acetate of aluminum. The patient rallied well and continued to improve until nine days afterward, when he began to have difficulty in swallowing. The next day there was considerable stiffness of the jaws, when he was given two doses of antitetanic serum at an interval of six hours. In addition I gave him gr. xv. each of potassium bromide and chloral every three hours as long as he was able to swallow. He was fed by means of a tube with a great deal of difficulty, the jaws being so rigid. At about twenty-four hours from the first appearance of the symptoms of tetanus, he began to have slight spasms. They continued more or less until his death, forty-eight hours later. They were not very severe, being manifested by a risus sardonicus and stiffening of the chest and arms at intervals of from five to ten minutes. The legs were not affected. He died of asphyxia twelve days after his accident. There did not seem to be any special improvement following the administration of the serum, though it may have had an effect in lessening the severity of the spasms. The difficulty in swallowing was the most marked symptom. This, I believe, is an unusual early symptom, but marks a severe infection.

Therapeutic Hints.

Tartrate of Piperidin is the most successful uric-acid solvent, having greater power than lycetol, piperazin, or urotropin.—E. HAWKINS, *Therapist.*

Typhoid Fever.—In children and young persons after convalescence an exaggerated growth of the long bones frequently occurs.—DRESCHFELD.

Epistaxis.—If compression is not effective inject a five- or ten-per-cent. solution of gelatin in artificial serum, or apply by means of a tampon.

Chorea.—Fowler's solution, ♏ xv. t.i.d., effected a cure in three children and one adult after an average stay of eighteen days in hospital.—CARTER.

Acute Bronchitis with difficult expectoration: caffeine 0.30 cgm. at bed-time, and during the day citrate or acetate of potassium every four hours in dose of 1.20 gm. to 1.80 gm.—EDGEWORTH.

Contraindications for Paracentesis of Membrana Tympani.—1. Presence of fluid in the middle ear without pain or fever. 2. Pain for twenty-four hours with congestion, but without fever or demonstrable presence of fluid.—PIERCE.

Antitoxin Dosage in Diphtheria.—Two thousand units should be given to mild cases; from 3,000 to 4,000 if the uvula and tonsils are affected: from 4,000 to 5,000 if the nares are involved. In all septic conditions 5,000 to 6,000 units of antitoxin should be given at once.—KOESTER.

Diagnosis of Appendicitis.—In most cases the diagnosis may be made upon the following symptoms being present: 1. Sudden onset in one previously well, with or without vomiting. 2. "Board-like" condition of right abdominal wall. 3. Pain at the McBurney point.—CHARLES B. PARKER.

Goat Milk has the advantage over cow's milk of being free from tubercle bacilli and can be taken quite fresh. Contrary to general opinion, the taste is not disagreeable if the animals are properly selected and properly kept, being considered of a more delicate flavor than cow's milk. The quantity of fats, casein, and salt varies greatly in the different varieties of goat. For infants and dyspeptics the weaker milk may be chosen, while the stronger answers better for debilitated subjects.—*Journ. de Méd. de Paris*, March 25, 1900.

Treatment of Locomotor Ataxia.—The treatment of tabes may be summarized as follows: 1. The determination whether anti-syphilitic treatment shall be undertaken. 2. The utilization of electricity, hydrotherapy, massage, and counter-irritation. 3. The education of the ataxic members, the rehabilitation of purposeful movements. 4. The administration of the iodide of potassium in tonic doses, nitrate of silver, and restoratives. 5. The relief of individual symptoms, such as pain, crises, dereliction of function of the bladder, ocular palsies, amaurosis, and trophic disturbances. 6. The adoption of a plan of treatment and carrying it through. This may be construed as psychical treatment if one so desires. However that may be, no one who has had experience in treating locomotor ataxia will be likely to deny its importance. —COLLINS.

Reviews and Notices.

On the Use of Massage and Early Passive Movements in Recent Fractures and Other Common Surgical Injuries, and the Treatment of Internal Derangements of the Knee Joint. Three Clinical Lectures delivered at St. George's Hospital. By William H. Bennett, F.R.C.S., Senior Surgeon to St. George's Hospital, etc. Reprinted after revision from *The Lancet*, with Twelve Illustrations. New York, London, and Bombay: Longmans, Green & Co. 1900.

We agree entirely with the author of this treatise as to the great value of careful and systematic massage in recent fractures and sprains. The use of massage in these conditions does not perhaps receive the attention which it deserves, and its value is therefore not sufficiently recognized. The first lecture of this series is designed to give directions how and in what class of cases massage is of most value, and the subject is well presented. There are several explanatory illustrations. The description of the treatment of sprains is very good, and the advice given is excellent. Many Americans have been using massage in these conditions for a long time, so that there is nothing very novel in the treatment, but a good presentation of the subject, such as this, is always useful. Displacement of the semilunar cartilages of the knee is the important internal derangement which receives attention.

The Present Position of the Treatment of Simple Fractures of the Limbs: An Address Delivered in Opening a Discussion at the Meeting of the British Medical Association held at Ipswich, August, 1900. By William H. Bennett, F.R.C.S., Senior Surgeon to St. George's Hospital, etc. To which is appended a Summary of the Opinions and Practice of about Three Hundred Surgeons. Reprinted after revision from the *British Medical Journal*, October 7, 1900. London, New York, and Bombay: Longmans, Green & Co. 1900.

The title page of this little volume explains what it is. The author's opinions upon the subject of fractures are advanced and sound and, in the form of this address, make interesting reading. The appended summary of the opinions of three hundred surgeons in various parts of the United Kingdom adds an element of interest, and gives us a good idea of what methods are looked upon with most favor by British surgeons.

Transactions of the American Gynæcological Society. Vol. XXV., 1900, 454 pp. Illustrated. Philadelphia: 1900.

The scientific transactions of the American Gynæcological Society for the year 1900 were of high value and interest. Almost the entire range of female genital diseases has been covered, and, in addition, there were two valuable contributions on the surgery of the ureters, by Petersen and Bovée. The work of the society was concluded by the personal reminiscences of the progress of gynæcology by Dr. T. A. Emmet. The volume is well printed and nicely illustrated.

The Essentials of Practical Bacteriology: An Elementary Laboratory Book for Students and Practitioners. By H. T. Curtis, B.S. and M.D. Lond., F.R.C.S., Late Surgical Registrar, University College Hospital; Formerly Assistant to the Professor of Pathology, University College, London. Pp. 291. London, New York, and Bombay: Longmans, Green & Co. 1900.

This volume differs in but slight degree from the many other works on the same subject. The author has, however, included some very interesting details concerning the etiology of cancer, ringworm, favus, etc., which are of intense interest to the microscopist and clinician. The book is well written, well illustrated, extremely clear, and practical.

On Some Cirrhoses of the Liver: being the Lumleian Lectures for the Year 1900. Delivered before the Royal College of Physicians, London. By Walter Butler Cheadle, M.A., M.D. Cantab., Fellow of the College; Senior Physician and Lecturer on Clinical Medicine, St. Mary's Hospital; Consulting Physician to the Hospital for Sick Children, Great Ormond Street. With Illustrations. Pp. 109. London: Smith Elder & Co. 1900.

Any contribution which can help us in the knowledge of diseases of the liver should be welcomed by the profession at large, and in this little volume before us we have a valuable work by one specially able to instruct us on these subjects. The work, although short, contains much valuable information, corrects many prevalent misunderstandings, and gives good, helpful advice. Special praise is due the eleven full-page colored plates which illustrate the pathological conditions discussed in the text.

The Medical Examination for Life Insurance and its Associated Clinical Methods, with Chapters on the Insurance of Substandard Lives and Accident Insurance. By Charles Lyman Greene, M.D., St. Paul, Clinical Professor of Medicine and Physical Diagnosis in the University of Minnesota. Pp. 426. With Ninety-nine Illustrations. Philadelphia: P. Blakiston's Son & Co. 1900.

This work has been written with a view to teach students and practitioners the full significance of all the questions asked on the usual insurance blank, as well as the proper method of gaining knowledge of the applicant's health. The technique of physical examinations of the chest is especially well formulated by the author, and some well chosen practical diagrams make the instruction unusually effective. The chapter on urine analysis is very complete and the best and quickest methods are fully explained. The book is interesting, and brings out much matter which ordinarily is not to be found in medical text-books. Its perusal will well repay even those not interested in insurance examinations; for those who are agents or examiners the work is invaluable. Heredity, the influence of occupations, the risks on substandard lives, and accident insurance are all well-treated subjects.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., assisted by Charles Adams Holder, M.D. Vols. II., III., and IV. 1900. Philadelphia and New York: Lea Brothers & Co. 1900.

The June issue contains articles on surgery of the abdomen, including hernia, gynæcology, diseases of the blood, diathetic and metabolic diseases, diseases of the glandular and lymphatic system, ophthalmology. The September number contains articles on diseases of the thorax and its viscera, including the heart, lungs, and blood-vessels, diseases of the skin, diseases of the nervous system, and obstetrics, while the last volume of the year covers diseases of the digestive tract and peritoneum, genito-urinary diseases and syphilis, fractures, orthopedics, diseases of the kidneys, physiology, practical therapeutics, etc. The list of editors for the various departments constitutes an almost formidable array of talent. Among the names are included those of William Ewart, Richard Norris, William Spiller, Henry Stelwagon, John Clark, William Coley, Edward Jackson, Alfred Stengel, Henry Baker, William Belfield, Joseph Bloodgood, John Bradford, Alfred Brubaker, Max Einhorn, and E. Q. Thornton. Each one has done conscientious work, and although some chapters show an easier manner of writing and a more facile flow of words than others, still in science one must not look for a constantly pleasing literary style. The most entertaining chapters, however, are those in which the editor shows, first of all, a deep personal knowledge of the subject in hand, and, secondly, does not refrain from throwing his personality into the work, and to dwell upon what he has himself seen and done to emphasize or refute the statements his position calls upon him to record. The work as a whole reflects merited credit upon the publishers and various writers; but, as we have previously pointed out, there is a certain drawback in having to wait a full year for the completed work. To be of the greatest value as a means of reference to current and recent literature, a year-book should cover all departments simultaneously. Still, when the last volume has been delivered, one has in this set of books a very complete *résumé* of the actual advances in medical and surgical science for the period which each volume represents.

Bacteriology and Surgical Technique for Nurses. By Emily M. A. Storey, Superintendent of the Training-School for Nurses, St. Anthony's Hospital, Rock Island, Ill.; Author of "Practical Points in Nursing," "Practical Materia Medica for Nurses," etc. Pp. 190. Illustrated. Philadelphia: W. B. Saunders & Co. 1900.

Like most of this author's works, the present volume is practical, telling neither too much nor too little, and is written in an exceptionally clear manner. The history of bacteriology, a general description of the varieties of bacteria and their relation to disease, the theory of antitoxins, antisepsis, disinfectants, and deodorants are the well-handled subjects in the first part. In the second half, a careful description and explanation regarding the care of the operating-room, the methods of sterilization, care of instruments, the lists of instruments possibly needed in the different operations, the proper methods of keeping charts or taking histories, and the method employed in making antiseptic

gauzes, etc., afford valuable reading to a nurse. Inflammation, catheterization, douches, enemata, preparation of a patient for operation, the sequels and complications met, and the signs of death and preparation for autopsies are all well described by one evidently thoroughly at home in the sick-room.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS, Fifteenth Session, held at Washington, D. C., May 1–3, 1900. Vol. XV.

THIS volume represents a series of papers, with detailed discussions embodying many practical suggestions on current topics, and will well pay a careful perusal.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

LONDON WATER QUESTION—THE COMPANIES' COUP—YELLOW-FEVER COMMISSION—PARLIAMENT, SMALLPOX, AND VACCINATION—GLASGOW EPIDEMIC—BRITISH MEDICAL CONSTITUTION—PLAGUE—BIRMINGHAM CHEAP CONSULTING SHOP.

LONDON, March 1, 1901.

POLLING for the county council is to take place to-morrow, so we are in the midst of electioneering excitement. It is true we are bearing ourselves very quietly, but the apathy of the London rate payer seems at last to be roused and this on a great sanitary question—the water supply. The companies which have so long enjoyed the lucrative monopoly of providing us with water, encouraged perhaps by the failure of the county council to obtain the control of this necessity of life, joined together in a demand which can be described only as an attempt at wholesale robbery. They proposed to compel every householder to put up a cistern and new fittings. The alleged object was to prevent waste—the hidden but real motive was to enhance the value of their monopoly in the prospect that they will soon be bought out. The cost of the changes has been estimated by competent engineers at nearly a year's rental of the house property of the metropolis—a matter of millions sterling, and these millions the companies wish to compel the householders to pay—although their representatives have had to admit that the change is entirely for their shareholders' benefit. They have so long battened on their monopolies and defied all efforts to improve this condition of things that they seem to have lost all sense of right and wrong. Perhaps they have gone too far, and the election to-morrow may be determined by a revolt of the rate payer with a mandate to the county council to end the robbery of the monopolists.

An official inquiry has been going on all the week as to the effect of the new regulations proposed by the companies. At this inquiry the witnesses for the companies have been obliged to make admissions which must condemn the proposal as one for deliberate extortion and which might wreck the government if sanctioned. Accordingly, yesterday counsel for the companies withdrew their scheme and then had the face to ask that their opponents should be saddled with the costs of the inquiry, and in the House of Commons last night, questioned as to this, Mr. Long said the expense incurred by local authorities in contesting the regulations could not be repaid. Thus the burdened rate payers are to be mulcted for resisting robbery. But perhaps more will be heard on this point; for the proposals are withdrawn only *pro tem.* A revised set of regulations is ready in the offices of the companies. It differs little from the others and may be sprung on the public at any moment. In fact, the present climb-down is only in the hope of influencing to-morrow's election. If the party which advocates the purchase by the county council is by this move left in a minority, a renewal of the proposals is certain to follow at an early date.

Then we may be once more asked to revert to the unwholesome cistern storage and undo the sanitary work of half a century. Doctors and hygienists have during that time been urging on the public the dangers of an intermittent supply and proving that cisterns were often death traps. For London to go back would be to fall from her high position in the van of sanitary progress.

An interim report of the yellow-fever commission, sent by the Liverpool School of Tropical Medicine, has a pathetic interest on account of the death of Dr. Walter Myers. Both the commissioners were attacked and Dr. Myers died. His colleague, Dr. Herbert Durham, therefore, submits for the present only a shortened interim report, showing the points on which the two had reached conclusions. Among these the first in importance is that they found in each of fourteen cadavers examined a fine small bacillus similar in diameter to that of influenza. It was present in the kidney, in the spleen, in the mesenteric, portal, and axillary glands, etc., taken from the bodies directly after death. It was often found in the contents of the lower intestine in extraordinary preponderance over other organisms. Other bacteria seemed absent from the organs in which this was present.

The bacillus has probably been seen by Sternberg, Freire, and Valle, but its importance has not been recognized, on account of the difficulty with which it is stained and grown on artificial media. It is also small and few in number.

Much search was made for protozoa, and the conclusion reached that yellow fever is not due to this class of parasite. It is admitted that much further work remains to be done before the final establishment of this fine bacillus as the cause of yellow fever, but the evidence in favor of it is stronger than that for any other germ. It is suggested that the acquisition of a new intestinal bacterium would explain the immunity of the acclimatized.

In parliament the war-hospitals commission was sure to be challenged. In reply to a question, Mr. Broderick promised to deal in an exemplary manner with any case in which it should be proved that a witness had been prejudiced by giving evidence. This will show you the animus that is exhibited in some quarters.

A similar animus has been shown by questions concerning smallpox and vaccination. Some of the allegations thus made were said by Mr. Wyndham to be absolutely without foundation. Notice has been given of a bill to promote easier exemption from vaccination. The government has refused to entertain any such question. Leicester and Gloucester have evidently continued their neglect of the one precaution available against smallpox.

Glasgow has a smart epidemic of smallpox, but this has been checked by revaccination, and it is hoped the diseases may have disappeared before May, when the exhibition is to be opened.

The constitution committee of the British Medical Association has issued its report. It is very lengthy and forms a heavy supplement to the *Journal*. This is unfortunate, as it is more likely than not to serve as a diminutive blue-book interment. Great changes are proposed, which are to be considered at the annual meeting, but which are already giving rise to discussion in the *Journal*.

Plague seems to be stalking from port to port and threatening all the lines of communication. It has been officially reported from Cape Town, Sydney, Aden, Hong-Kong, and Singapore. The isolated cases in our own ports have illustrated the readiness of our officers of health. But the occurrence of cases in Cape Town is a much more serious thing and is giving rise to grave anxiety. Fresh cases were announced yesterday.

The Birmingham Consultative Institute is not yet dead. Its committee lately met, when Mr. Arthur Chamberlain, its promoter, took the chair and uttered a foolish threat, that if the medical council deprived their consultant of his means of living the feeling of the committee would be to appeal to a high court of justice. Of course it is safe for Mr. Chamberlain to defy the council as he has defied the feeling of the profession. Dr. Irvine, however, may perhaps decline to do so. If not—well, who knows? Perhaps the council may once more exhibit its pusillanimity—possibly not.

OUR PARIS LETTER.

TO THE EDITOR OF THE MEDICAL RECORD.

TREATMENT OF CHRONIC DYSPEPSIA BY PHOSPHORIC ACID—THE PARIS WATER SUPPLY—TREATMENT OF INTESTINAL PERFORATIONS IN TYPHOID FEVER—CAUSES OF DEATH IN TYPHOID FEVER—FIGHT AGAINST ALCOHOLISM.

PARIS, March 10, 1901.

SIR: The Society of Therapeutics has been discussing recently the treatment of neurasthenia, and Professor Bardet, who is one of the best known pharmacologists in France, spoke of what he considered one of the most frequent causes of this illness, *i.e.*, chronic dyspepsia. In a great number of cases this condition is brought on by an abuse of nitrogenous food, and hyperacidity is thereby induced. In such cases hypoacidity in the fluids of the body is favored, and the best means of controlling this condition is to diminish the quantity of albuminous foods.

Some physicians, like Albert Robin, recommend the use of phosphoric acid, which is administered in doses of from one to three grams daily. No serious accident has been caused so far by the use of this drug; in some cases, however, a certain laxative action is produced, which may be useful when there is constipation, but should be avoided when there is any sign of irritation of the intestine. Professor Mathieu, who is a well-known specialist for stomach

affections, recommends using albuminous water made with the white of eggs, as a means of hiding the acid flavor of the drug. The solution should, of course, be rather weak. In some cases pepsin may be added.

It should be remembered that some patients cannot stand such large doses, and that it is well sometimes not to prolong the administration of the drug.

An important question for the hygienist is that of the drinking-water of a city, and a recent article in the *Presse Médicale* on this subject, in so far as it concerns the city of Paris, is of some interest, as it shows how the water supply has been established, and what methods have been employed to make it as pure as possible. In former times the supply was furnished in a very primitive manner. There were, it is true, some eighty public fountains where water was to be found, and then there was the water coming from the springs to the south of Paris, and brought into the city by means of the old aqueduct, built by Julian the Apostate and renovated by Henry IV. There were some other springs, too, to the north of Paris, coming from the heights of Belleville and Menilmontant, and used by the monasteries of St. Lawrence and St. Martin-in-fields, and, later on, under the reign of Philip Augustus, furnishing water to the celebrated Fontaine des Innocents. At that period Seine water was extensively employed—6,800 cubic metres of it out of a total supply of 8,000. In 1802 Bonaparte decided upon the construction of the Ourcq Canal, which was to bring to Paris the greater part of the drinking-water. For a number of years nothing was added to the supply, but in 1854 an artesian well was dug in Grenelle. The population of Paris was then 1,100,000, and there were only 80,000 cubic yards, which made 70 litres for each inhabitant per diem. A familiar figure in the streets of Paris at that time was the water-carrier, who charged 90 centimes, or 18 cents, for a cubic yard of water. Typhoid fever and cholera were then very rife. In 1854 Baron Haussmann was entrusted by Napoleon III. with the position of prefect of Paris, and as such called to his aid a civil engineer, Belgrand. Paris, in 1855, had a water supply of 80,000 cubic metres, and at the moment of Belgrand's death it had been increased to 370,000 cubic metres. The main idea in Belgrand's plan was to have two distinct set of pipes and reservoirs by which the water should be distributed, one set for the water used for the streets, the cleaning of stables, courts, etc., and another set for household use. Unfortunately, this idea has been only partially carried out, and there still remain communications between these two systems by means of some ten sets of apparatus, which are, however, to be done away with shortly. During the winter the water in Paris is good, but during the latter part of August and the month of September it is sometimes found necessary to employ river water, which, however, is filtered. The results furnished so far by this proceeding have been far from satisfactory. The real important transformation that is requisite is to find means of having special reservoirs for river water at a sufficient height to permit of its being used in every part of the city.

Amongst the different springs used for furnishing drinking-water in Paris, the most important is the Vanne, which furnishes water to the town of Seres. Typhoid fever having broken out in this town as well as in Paris, it was easy to understand that the water at fault was that of the Vanne.

At a recent meeting of the Surgical Society of Paris the question of intestinal perforations was broached, and Professor Lejars spoke at length on the subject. The diagnosis of this complication would seem to be rather difficult, and yet it is of the utmost importance that the diagnosis should be made as soon as possible. According to this report, and, as Dr. Loison said, the three cardinal symptoms are: (1) a sharp abdominal pain, more or less violent and localized; (2) a sudden rise or fall of the temperature; and (3) a change in the character of the pulse, which becomes more frequent and smaller, though remaining regular.

Dr. Loison has collected ninety cases of operations, with seventy-four deaths and sixteen cures, a proportion of 21.3 per cent. This is not so bad a result if one considers the fact that death almost always results from an expectant treatment. If the perforation takes place in the first stages of the disease, the prognosis is more grave, according to Dr. Routier, surgeon at the Necker Hospital. As to a speedy operation, there is no question as to the advisability of its being carried out as soon as possible, as out of the sixteen recoveries reported ten were from operations in the twenty-four hours following perforation.

A military surgeon, Dr. Reutlinger, has just published an interesting article on death in typhoid fever. The author had recourse to three hundred and fifteen autopsies. During the first week the mortality was almost nil, but increased rapidly during the second and third weeks. In forty-seven per cent. of the cases, death was supposed to be due to a hypertoxic condition, as there were no distinct lesions. In thirty-five per cent., death was due to intestinal hemorrhage or perforation. In five per cent. of the cases, diphtheria, erysipelas, or dysentery was the cause. Sudden death generally takes place toward the nineteenth day. This event is rarely preceded by changes in the pulse, but convulsions or syncope may be observed. But a fact to be insisted on is that one never found any trace of cardiac thrombosis or pulmonary embolus, either of which is generally supposed to be the cause of death in some cases.

The fight that has been going on against alcoholism in France is beginning to enter a new phase. The principal obstacle to be found to any change in the present laws is that so many of the electors earn their living from wine and alcohol producing, and this prevents any radical measure being taken. Last year the minister of war forbade the sale of intoxicating drinks in the barracks, and the minister of public instruction has advised teaching in schools the dangers of alcoholism. In one regiment the colonel has organized a temperance competition, which is to last several months, between the different companies of his regiment. Some railroad companies are going to suppress the sale of liquors to their employees inside the stations. Public speeches are also being made at Nantes, at Amiens, at Chateauroux. But there is one point on which no definite conclusion has been reached: it is as to the real action of alcohol when given to workmen who are underfed. Some experiments recently carried out would tend to show that it is better to abstain completely from any such means of stimulation.

"TUBERCULOSIS IN PRISONS AND REFORMATORIES."

To the Editor of the Medical Record.

Sir: In the Medical Record of March 3, 1901, appeared a very interesting article with the above caption by Dr. S. A. Knopf; and since it treats of a subject with which I have had to deal both in a professional and official capacity, I should like to reinforce the author's arguments by the presentation of a few facts. To begin—and to give the reader an idea of the manner in which the Huntsville prison is conducted—I shall quote from my biennial report of November 31, 1900, viz.:

"I find no necessity of offering recommendations—or even suggestions—looking to the betterment of the sanitary and hygienic conditions of the prison, since the indefatigable work and careful attention of other officers have already accomplished all that could be desired. I have all along noted with satisfaction and pleasure the scrupulous cleanliness of the cell buildings, bedding, grounds, and other buildings of the prison. This commendable attention to the details of cleanliness is one of the primary factors in the preservation and maintenance of health, and is conducive to the reduction of disease among the inmates to its minimum of destructiveness. The water and ice furnished meet every requirement. The food has been amply sufficient in variety and abundant in supply, and has been served in the best manner possible. . . . In December of last year the consumptives of the penitentiary system were congregated at the Wynne Farm, where every necessary provision has been made for their care and treatment. I am convinced that the isolation of these unfortunates was a wise and humane act, alike to the sick and well; for it is a well-established fact that consumption is an infectious disease. The bacilli in the sputa and other emanations of the body of one thus afflicted may readily find lodgment in the tissues of a healthy person and set the seal of suffering and early death upon him. If one so affected should happen to be in the enjoyment of good health—his power of digestion and assimilation of food being in a normal and vigorous condition—there is a possibility that the resisting-power of the system may be able to throw off the poison and thereby thwart its ravages. In this disease the lungs are the favorite seat of attack, because its germs, being blown about in the dust, more easily reach the air-passages. But even then the bacilli may become encysted and held in abeyance for an indefinite time, provided the subject is of strong constitution, and is not tainted with any of the causes that predispose to consumption. In such cases it is possible to eventually effect a cure; provided, further, that the hygienic conditions encompassing the subject are of the most favorable character. And, while the lungs are the favorite seat of attack, they commonly furnish the media for the infection of others. For, once the tubercles in the lungs break down, the immediate result is a softening of the lung tissue, which, in the form of a semi-purulent matter, is cast off in the frequent acts of coughing. This matter, becoming dry, fills the air that is breathed in the form of an amorphous or impalpable powder. The proper recognition of this fact would of itself

warrant the removal of such sufferers from among the great number of healthy prisoners. And again, the experience of all medical men of the present day, who have made the subject of consumption one of special investigation and study, has taught them that the open air and outdoor exercise regimen is the chief factor in holding in check this dread disease, and forms the only foundation upon which to rest the hope of ultimate recovery. . . . In consideration of these facts, I am convinced that the events of the future will abundantly prove the wisdom of the act of separation. Indeed, I think that a careful study of the mortality tables, as compared with those of my honorable predecessors, will show that good results have already been realized. In the biennial report of this hospital ending October 3, 1898, it was shown that twenty-one had died of consumption. During the two years ending with this report only eight have so succumbed—before the separation. Add to this number ten deaths at the Wynne Farm, and we have a total of eighteen as against twenty-one, notwithstanding an increased prison population."

In the quotation from the report certain facts are revealed, as well as my views on the subject of the importance of isolating consumptive prisoners. At the date of the report there were in the Texas penitentiary: Whites, 1,630; negroes, 2,323; Mexicans, 518; Indians, 3. Since among the whites are representatives from almost all civilized countries, it will be seen that the Texas prison is quite cosmopolitan in character. But a word on this point. Many of these men come from the ranks of the tramp army. Like migratory fowls, these unfortunate people drift south to spend the winter. Some of them are consumptives, and come south to escape the severity of northern winters. Possibly some of them come with scanty means, seeking the recovery of health. But be that as it may, many of them bring up in prison. They are generally men who have been exposed to all manner of dissipations and want, and are, therefore, fertile soil for the vigorous growth of the tubercle germ. The negroes of the South are for the most part careless and indolent. Most of them live in miserable huts and are at all times underfed; and it would surprise the northern physician to come here and see the very large percentage of negroes that is tainted with venereal diseases of varying stages and character. Such beings are, of course, the favorite subjects of the bacilli of consumption. The Mexicans come from the western prairies where as rancheros they have seldom known the comforts of a home; but, being the true children of nature, they are for the most part healthy when received. But, like the Indians who were put in the comfortable dormitories of government schools, they are unfit for cell buildings, hence it appears to be no hard matter for the Mexican to become infected with tuberculosis.

Add to the above characteristics of convicts the fact that many are received suffering with consumption—even in the last stage—and it will not be difficult for the medical man to understand that the disease here became a problem of no small moment, and the quotation from my report shows how we have tried to solve it.

The Wynne Farm is situated well beyond the limits of the city of Huntsville, and is an ideal location for the purpose for which it is used. The men sleep in a large open pavilion or stockade where each one has a quantity of fresh air, almost equal to that he would enjoy if "camping out." The kitchen and spacious dining-room are also constructed so as to admit of the free circulation of air. All the buildings are kept clean and the whitewash brush is never permitted to lie in idleness. Cheap spittoons are used, which are kept disinfected by a liberal use of chloride of lime and carbolic acid. When the men are out the pavilion is thoroughly fumigated with the vapors arising from the mixing of these two chiefs of disinfectants.

Every day that is free from damp and chill, every man who is able to do so is expected to occupy his time in some light work in the orchard, garden, or farm. If one is not able thus to exercise, he is required to sit out in the porches, walk about the yard, etc.

These men are required to bathe often. They are supplied with comfortable and suitable clothing which is kept clean by frequent washings. The food consists of vegetables, poultry, beef, bacon, rice, oatmeal, fruits, etc., all of which is properly cooked. Fresh milk and butter we have in abundance, with coffee and tea.

When any of the men are very weak, they are given whiskey *pro re nata*. As to medicine, I rely on cod-liver oil with creosote and hypophosphites—treating symptoms and complications as the cases may require.

So far the results have met every expectation, and more, for the garden and farm products of these consumptives have been more than sufficient to pay for their keep; and the physician interested in the subject of tuberculosis would be surprised to note the wonderful improvement in the great majority of the patients. Many who were sent there a little more than a year ago suffering with incipient phthisis are now, so far as both subjective and objective evidences may be relied upon, entirely well. Others, who went there apparently in the last stage, reduced in flesh and strength as a result of frequent hemorrhages, are now strong and in good physical condition. Men have gone there so reduced in strength as to be unable to walk twice across the room, whose eveuing temperatures would reach 103°–104° F., and who, in less than three months would be entirely free from fever, aud able to do light work.

I take it that no physician of the present day will question the correctness of a move such as we have made, and I think I have shown that it is not only feasible but profitable to separate convicts suffering with consumption from those not so infected, and certainly humanitarian considerations would demand it. Some are cured, others have their lives prolonged, all are rendered more comfortable, and the nou-tuberculous convicts are protected. In closing I would state that it appears to me that consumptive convicts do better under proper conditions than do those who are free. One of the chief reasons for this is enforced regular habits and mode of living. They are not exposed to night air nor the nightly excesses that many free men indulge in. We all know that the sexual desire of the tuberculous man is often augmented, even after he has grown too weak to relieve it; and there is little doubt in my mind that an overindulgence in this respect often shortens life. Here, however, there are no excesses, and no one is required to labor beyond a degree that constitutes proper and healthful exercise.

To conclude, I will say that when a proper amount of exercise (without fatigue), fresh air, and sunshine fail to benefit the consumptive, there is little to hope for this side of the peace of the grave.

W. E. Fowler, M.D.
Physician to the Huntsville, Texas, Penitentiary.

Huntsville, Texas, March 6, 1901.

MARRIAGE AMONG LEPERS.

To the Editor of the Medical Record.

Sir: What is the general opinion of the medical profession in America on the advisability of allowing lepers to marry? Should it be allowed or forbidden?

M. B. Carleton, M.D.,
Superintendent Leper Asylum.

Sabathu, India, February 6, 1901.

HYDROGEN PEROXIDE IN APPENDICITIS.

To the Editor of the Medical Record.

Sir: On page 392 of the Medical Record for March 9, 1901, Dr. Miller states his belief that the employment of hydrogen peroxide was responsible for the death of an appendicitis patient, and I am quite sure that the surmise is correct. "The case did well up to the eighth day, and on this occasion the hydrogen peroxide did not escape so freely as it had at the previous dressings. The temperature commenced to rise, and within forty-eight hours the patient succumbed to suppurative peritonitis." My comments will be brief. Hydrogen peroxide used freely at the moment when the operator arrives at a pus collection will blow out the pus instantly. Salt solution is then used for flushing away the foam, and the field is clear. This technique allows one to work with celerity and with a minimum degree of disturbance to the patient—a very desirable point in pretty appendicitis work. If there are multiple pus collections present, they can be evacuated promptly one after the other, and the operator can be very comfortable in the feeling that he is not going to infect the peritoneum in subsequent manipulation of structures in the infected area. The mechanical advantages of hydrogen peroxide for instantaneous cleansing purposes are apparent. There is another feature that should also be appreciated at a glance by any one with mechanical instincts. If the rapidly expanding mass of foam is not given free escape externally, it will go somewhere else. One need not study both Ganot and Deschanel in order to fix this point in mind. If hydrogen-peroxide foam is given a line of least resistance by the operator, it will follow that line.

I have seen this "sheet anchor of success" used on the wrong side of the ship very often. Not long ago one of my own assistants injected peroxide into a deep fistula of the leg after opening an abscess, and the peroxide promptly did what was to have been expected. It escaped widely into the loose connective tissues and produced a large new area for infection. Hydrogen peroxide properly employed seems to me to be really a necessity for successful work in appendicitis cases with pus. It is not proper to use this resource continuously for several days in succession, because it destroys new lymph that is needed for repair. It destroys granulations that are needed for repair. Further, it is not mechanically proper to use peroxide in any cavity

from which the foam cannot escape freely. A detailed description of the way in which peroxide may be employed usefully is given in my work on the subject of appendicitis and the accompanying statistics are offered in evidence.

In the case that Dr. Miller quotes, peroxide used up to the eighth day must have been interfering with wound repair during all of that time, and on the eighth day, when the external opening of the wound had presumably become contracted, peroxide injected into the bottom of the cavity probably followed natural laws, and did what might have been anticipated.

ROBERT T. MORRIS.

New Instruments.

A NEW SACCHAROMETER AND UREOMETER COMBINED.[1]

BY A. ROBIN, M.D.,

NEWARK, DEL.,

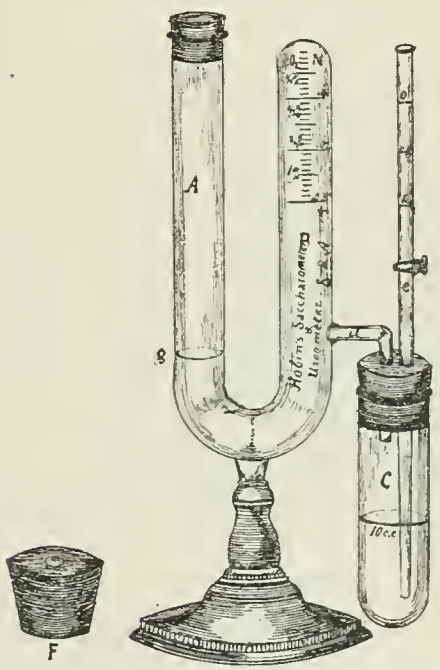
PATHOLOGIST AND BACTERIOLOGIST TO THE DELAWARE STATE BOARD OF HEALTH LABORATORY.

ANY one who has been working with Einhorn's saccharometer has no doubt convinced himself of its inaccuracy. The principle on which this saccharometer is based is faulty. As soon as fermentation takes place, the fermenting liquid is displaced into the bulb at the free end of the tube, and a variable amount of gas escapes. The amount of CO_2 thus lost will depend upon the rapidity with which fermentation and consequent displacement of the liquid progress. To obviate this loss of gas, which cannot be determined directly or indirectly, thus rendering the results uncertain, the following apparatus was devised:

A U-shaped glass tube (*AB*) with a small side tube (*d*) is connected by means of a rubber stopper (*F*) with a test tube (*C*) of a capacity of 20 c.c. (see figure). The diabetic urine is diluted with water until it reaches a specific gravity of 1,020, the volume of water as well as its relation to the volume of urine being noted, and the results multiplied by the number of dilutions. The U tube is then filled with water to the mark (*g*). To do this the index finger is placed on the free end of the side tube (*d*), the arm (*A*) is filled with water which is forced into the arm (*B*) by inclining the apparatus. The upper end of *A* is then closed by a cork, and the finger removed from the side tube. The apparatus with the rubber stopper on the side tube (the latter should be covered with a little vaseline to prevent the possible escape of gas through the perforation), but disconnected from the test tube (*C*), is placed in the stand and set aside. Ten centimetres of the urine are placed in the tube *C*, a tiny crystal (about 0.05 gm.) of tartaric acid is added, and 1 gm. of Fleischman's yeast incorporated by means of a glass rod. The addition of the tartaric acid inhibits the growth of bacteria which may modify the fermentation, and the latter results from the yeast alone, thus rendering the results more uniform. This done, the test tube is connected with the apparatus, the rubber stopper being pushed in as tightly as possible. While this is being done, a few air bubbles escape into the arm *B*, but they are removed by inclining the apparatus, until they are forced out into *A*. The cork should be removed from the upper end of *A* and the apparatus set aside in a moderately warm place. In about twenty to thirty minutes, fermentation will commence and gas bubbles begin to accumulate in the upper end of the arm *B*. At the end of twenty to twenty-four hours fermentation is complete, and the volume of gas multiplied by the number of dilutions represents the approximate amount of sugar. This, of course, has been determined empirically. When fermentation is complete and negative pressure is established in the tube *C*, some of the water from arm *A* will flow back into *C*, but this does not affect the volume of gas in *B*. It will be noticed that the gas in *B* is not pure CO_2 but composed largely of air. The object of displacing the latter is self-evident. As CO_2 is quite soluble in water, it becomes necessary either to collect the gas under mercury or substitute a gas insoluble in water. It is seen that the tube *C* has twice the volume of the fermenting liquid; the volume of air above the liquid is about equal to the volume of CO_2 generated when only one per cent. of glucose is present. While fermentation is going on, the air from *C* is displaced and collects in *B*, thus largely minimizing the error concurrent with a variable absorption of the CO_2 by water. However, if for any reason it be desired to obtain CO_2, or any other gas, in a pure state, it may be done by filling the U tube with mercury instead of water, filling the tube *C* up to the stopper and rejecting the first few bubbles of gas which represent the air in the side tube.

[1] From the State Board of Health Laboratory.

The following comparative experiments made with the author's saccharometer and that of Dr. Einhorn



Saccharometer and Ureometer combined. The figure shows the apparatus set up as a Ureometer. *F*, The rubber stopper used for the saccharometer.

show the marked difference between the two, as well as the inaccuracy of the latter. The tubes were of equal dimensions and calibration, made by Eimer and Amend, New York. The same amount of yeast and glucose were used and other conditions were identical. The reading was taken at the end of twenty-four hours.

Glucose Solution, per cent.	Author's Saccharometer, Divisions of the Tube.	Einhorn's Saccharometer, Divisions of the Tube.
½ in water	2.8 (½ per cent.).	1.0 (¼ per cent.).
½ in water	2.6 (½ per cent.).	1.4 (¼ per cent.).
½ in water	2.6 (½ per cent.).	1.6 (¼ per cent.).
½ in urine	2.1 (½ per cent.).	1 (¼ per cent.).
½ in urine	2.1 (½ per cent.).	1 (¼ per cent.).
½ in urine	2.1 (½ per cent.).	1 (¼ per cent.).

Owing to the larger amounts of gas collected with the author's apparatus, a larger tube was found necessary. It then occurred to the author that this apparatus could be rendered still more useful by making it serve the purpose of a ureometer as well. The U tube being a collecting tube for any kind of gas, it was evident that nitrogen could be collected in it as well as carbon dioxide. Of the various ureometers on the market the most satisfactory is Doremus' improved by Hinds. It

was therefore deemed advisable to take the latter as a pattern. Accordingly, the arm *B* was made of the same size and calibrations as Doremus', and a stopper with two perforations substituted for the one used in collecting CO_2.

To use the apparatus as a ureometer proceed as follows: 1. Fill the U tube with water as described above. 2. Put the rubber stopper on the vertical limb of the side tube. 3. Fill the tube *C* to the 10 c.c. mark with the hypobromite solution.[1] 4. Connect the apparatus with the tube *C*. 5. Place the graduated pipette into the second perforation, leaving the stopcock open so as to allow the displaced air to escape. 6. Close the stopcock and slowly remove the cork from *A* (if a bubble of air is forced into *B* remove it by inclining the apparatus, with the index finger on the free end of *A*). 7. Fill the pipette with urine to the 0° mark, by means of a dropper. 8. Open the stopcock and allow 1 c.c. of urine to flow into the test tube *C*. Close the stopcock.

The urea will be decomposed by the hypobromite solution, and at first air, and then nitrogen will escape into the arm *B*. When no more gas bubbles are seen to generate in *C* the reaction is at an end, and the volume of gas in *B* is noted, deducting from the total amount two divisions of the tube for the air displaced by the 1 c.c. of urine. Thus, if the volume equals 0.02 or two per cent. the actual volume of N would be only 0.0118, or 1.8 per cent.

It is thus seen that in this apparatus we have a combination which makes it not only doubly useful but reduces the cost to a minimum. The physician who is not doing enough of uranalysis to justify the purchase of two pieces of apparatus will find this arrangement especially serviceable. Another advantage of this form of ureometer over that of the improved Doremus' is that not only can it be kept cleaner, but in case any of the parts break they can be readily replaced at a trifling cost.

This apparatus is manufactured exclusively by Messrs. Eimer and Amend, New York, to whom the author is greatly indebted for their able execution of his designs.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 16, 1901:

	Cases.	Deaths.
Tuberculosis	327	189
Typhoid fever	19	10
Scarlet fever	608	29
Measles	234	6
Diphtheria and croup	324	58
Smallpox	37	6
Varicella	78	0
Cerebro-spinal meningitis	0	5

An Old-Fashioned Doctor.—The Sunday *Sun*, February 23d, contained the following well-deserved appreciation of the old-time physician, exemplified in the person of the late Dr. Hornbeek. "The old-fashioned doctor who combined the duties of nurse and physician, and who was indifferent to considerations of comfort, careless of fees, and unconscious of the social or business status of his patients, has become almost a tradition. He exists in only a few localities. Dr. Philip Du Bois Hornbeek, who recently died in the town of Wawarsing, Ulster County, was a fine example of this type of practitioners. When Dr. Hornbeek began to practise in Wawarsing, half a century ago, there were no specialists. Like the old doctor of Drumtochty, he looked after all the organs of the body, and served as accoucheur, dentist, surgeon, and druggist, with equal skill and success. Like many old practitioners, Dr. Hornbeek was soft of speech and gentle in manner. His very presence in the sick-room soothed and cheered. When the case was critical and the life of the patient hung trembling in the balance, Dr. Hornbeek would sit at the bedside day and night, noting every symptom. In his mild and kindly way he would encourage and stimulate the sufferer, and, if it were humanly possible, bring him back to health again. For years Dr. Hornbeek rode horseback over the roughest regions in the wild and hilly district where he lived. He was a noble man and an excellent type of a stamp of physician fast dying out."

The Use of Opium, Ganja, and Intoxicating Drinks in India.—Drunkenness has always prevailed in India among certain classes, but as a nation the people have been temperate for many centuries. It is deeply to be regretted that of late years drinking-habits have been acquired by some educated Hindus, whose forefathers never touched intoxicating liquors. This is largely attributable to European example. The British government revenue from the sale of toddy, opium, bhang, etc., is immense.

Pasteur's Statue.—It has been erroneously announced, says the *Pharmaceutical Journal*, that M. Antonin Carlés has completed the model of the monument which is to be erected to the memory of the great Pasteur in his native town, Dôle. According to an interview published in *La Presse*, the sculptor declares that the statue will not approach completion for several months yet, and that it certainly will not be erected before the end of next year. It may not be out of place here to give an outline of the work. At the foot of the monument is a woman, whose appearance denotes suffering and distress, holding to her bosom two young children, who have been snatched from death, and listening attentively to the voice of Science, who reveals to her the universal benefits conferred upon mankind by the illustrious savant. At her side another woman personifying Science tenders, with a magnificent gesture, a wreath of laurel toward Pasteur, who, standing erect in a meditative attitude, dominates the whole. The effect is wonderfully striking and significant.

Bacteriology of Distemper.—If Dr. Copeman's researches are confirmed, the micro-organism of distemper in dogs has at last been isolated. He has succeeded in isolating a small cocco-bacillus, the introduction of which subcutaneously into healthy dogs produces the disease within a week. Working with this organism, a vaccine has been prepared, which Dr. Copeman states is capable of protecting against attacks of the disease. Many members of the medical profession will, perhaps, doubt the utility of devoting energy to the study of the diseases of dogs, when so much still remains to be accomplished in human pathology. We would remind such objectors that anatomy has been most successfully studied in animals, and that the best of our knowledge of human physiology is derived from investigations carried out in dogs. With our present imperfect conceptions of pathological processes, it is not the individual case that will enlighten; advance can be made only by

[1] This solution is best prepared extemporaneously. Have on hand a solution of sodium hydrate, 100 gm. in 250 c.c. of distilled water. To 5 c.c. of this solution add 1 c.c. of bromine; stir gently with a glass rod until the latter is dissolved and add 5 c.c. of water.

widening our conceptions, and so obtaining material for generalization. From such a point of view such work as Dr. Copeman's is most valuable.—*Medical Press.*

The Medical Profession for Women.—This subject is discussed in an interesting paper by Marie A. Belloc, in the January *Leisure Hour.* The writer estimates that for women who can face the expense and the long time required for training, the medical profession affords an excellent opening; not only is this so in India, but there is certainly some opening on the Continent for British medical women. A lady doctor, half French or half German, could build up a large practice there. Paris has always favored women doctors. The writer also insists that a woman finds it far easier to build up a practice, even in England, than do her male competitors, chiefly owing to there still being few women doctors and their novelty itself helping much to making them known.

Longevity in Spain.—Spain as a nation may be dying or decaying, as Lord Salisbury somewhat bluntly put it, but, if statistics are to be believed, her people individually are among the longest lived in the world. *The British Medical Journal*, in its issue of February 16th, gives a list of the patriarchs in one part of Spain culled from the voters' tables. Asturias is the particular province which holds the record for the largest number of centenarians, and it is to be doubted if any district of similar size on earth can show so large a number. Each of the electoral districts of Langreo, Morcin, Grado, Villaviciosa, and Carreno has one centenarian. Siero and Oviedo have each two, Salas has electors aged respectively 101, 103, and 104. Cangas de Tineo has still more venerable triplets of 101, 105, and 106. Boal has two, aged 101 and 102; Franeo, one of 107; Valdes, two of 105 and 107; Pitona, two of 102 and 104, while Parres holds the record with three fine relics of antiquity, aged respectively 103, 105, and 107. This single province rejoices in no fewer than twenty-five centenarians in a total population of 600,000.

Alcoholism and Depopulation.—Alcoholism and depopulation are two subjects which at this moment excite the absorbing interest of humanity. It is, therefore, interesting to inquire what relation there is between them. From the fact that France is the country in which alcoholism prevails most, and in which the population increases least, it would appear that alcohol is a considerable factor in depopulation. Many authors, such as Lanceraux, Legrain, Jacquet, Pinard, and Debove, have launched anathemas against alcoholism from this point of view. M. Ovize, of Lyons, who has tendencies toward the rehabilitation of alcohol, claims that alcoholism, though a very ancient practice, has never prevented the population of the earth from increasing. Alcoholic excess, he says, has existed from time immemorial among the Hindoos and Persians. The laws of Manu and Lycurgus attested in their day the abuse of alcohol. It was regarded as hurtful, but hurtful only to the health of the individual and not to his descendants. However this may be, M. Ovize is forced to bow before the statistical results given by the life-assurance companies, which show greater longevity among abstainers; on the other hand, it must be admitted that the birth rate is at its minimum in Normandy, for instance, where the consumption of alcohol is very high, and at its maximum in other parts of France, where the consumption of alcohol is less. Beyond doubt there exist legislative provisions which may play a very important part either in combating or in favoring depopulation; but it must be admitted on the evidence of facts that alcoholism is, in this last-named case, one of the most active causes; it uses up the human race at both ends, so to speak, by increasing mortality and diminishing the birth rate or producing only degenerate offspring. Therefore, the writer of the article says, I cannot subscribe to the opinion of M. Ovize that the chief cause of the depopulation of a country is to be traced to economic causes, and in no way to alcoholism.—European Edition of *New York Herald.*

Some Remarks on X-Ray Diagnosis.—W. W. Graves says that there is no diagnostic procedure which requires more painstaking and more attention to detail than a successful *x*-ray examination. It is the popular idea, and believed in by many physicians, that it is easy to make an *x*-ray examination. Only those who have had experience in this line of work best know of the difficulties to be overcome. It is easy to make an *x*-ray picture which will satisfy the curiosity, but it is not easy to make an *x*-ray examination that fully satisfies the exacting demands of diagnosis. Roentgen's light may be, and is, of much value in medical and surgical diagnosis, but in order that its possibilities shall be fully realized, it will require work, work, work, on the part of its devotees.—*St. Louis Courier of Medicine*, January, 1901.

Experimental Pancreatitis.—Simon Flexner states that the results of the experiments (given in detail) lead to the conviction that (1) hemorrhage *per se* is a common condition in all forms of pancreatitis; (2) when it is excessive, it dominates the process; (3) it is usually more pronounced than are the inflammatory lesions, and the two conditions may be separate and distinct in the same organ or parts of the organ; (4) fat-necrosis is due to perversion of the pancreatic secretion and the direct result of the action of the fat-splitting ferment. Owing to the severity of the means used to provoke pancreatitis in experimental cases, it is not to be supposed that hemorrhage would commonly occur independently of inflammation of the gland; and this is found to be the case. Disintegration of the pancreatic tissue is one of the results of free hemorrhage. If we recall the tendency of the pancreatic secretion to act upon the pancreas, it follows that these injured foci might easily become the starting-points of another form of degeneration which would lead to necrosis of the gland and to reactive inflammation; that this dead tissue might then in turn form a favorable point for the location and multiplication of micro-organisms, whose presence would still further complicate the process.—*University Medical Magazine*, January, 1901.

Two Cases of Amblyopia following the Use of Jamaica Ginger.—John Dunn reports these cases, one of which was in a boy aged nineteen years, the other in a man aged thirty-nine years. The former drank two bottles of Jamaica ginger and some essence of lemon, while the latter drank four bottles of the ginger and some paregoric. The object was to "sober up." The two cases were seen, one four, the other two months after the attack. In both there was optic atrophy with changes in the diameter of the retinal vessels. The history is as follows: The attack begins with nausea and vomiting, which are followed after a varying length of time, "twelve to forty-eight hours" (Woods), by total blindness. This blindness is preceded by dimness of vision. At this time there are no visible changes in the fundus. As a rule, the vision after a few days is partially restored. Neuritis may be demonstrable in the fundus after a few days, going on to atrophy. The vision after a few months seems to grow worse rather than better, and suggests nerve-fibre degeneration. The pupils, when the blindness is not absolute, respond directly, consensually and in accommodation. The field of vision has nothing absolutely characteris-

tic, there may be more or less concentric contraction for white, with a central scotoma, or, as in this second case in which vision was reduced to $\frac{8}{200}$, there could be demonstrated no contraction of the field for white. The color tests are inconclusive. While in the cases we have accurate accounts of the appearances in the fundus as seen after atrophy has set in, we have no satisfactory detailed description of the changes in the fundus visible during the first few days after blindness occurs; nor has in any case the microscope had its say as to what the changes really are.—*Virginia Medical Semi-Monthly*, January 25, 1901.

Treatment of Lead Poisoning by Electricity.—J. Auriol Armitage reports the results of the use of the electric bath in cases of lead poisoning. The patients are all in lodgings, practically outside of control, so that late hours, drink, and standing on the damp ground at football matches have caused not a few relapses. Many of them having wives and families practically destitute have insisted upon returning home before they were completely cured. Notwithstanding these drawbacks, there were thirty-seven cures, either partial or complete, out of forty cases. The author gives the details of the treatment, and full reports of typical cases.—*The Birmingham Medical Review*, February, 1901.

A Case of Asthma Associated with Prolapse of the Liver.—H. B. Anderson reports a case in which the first real attack of asthma followed pneumonia. That the hepatic prolapse aggravated, if it did not actually occasion, the asthmatic attacks, there can be no doubt. The patient noted this fact himself, and so long as the liver remains in place he is comfortable. Moreover the asthmatic attacks are always improved by treatment directed toward the replacement of the organ. Whether the prolapse acts directly as a cause, or indirectly by producing the gastric disturbances noted before the attacks, it is impossible to say. Probably the reflex disturbance produced in each of these ways would play a part. At present an attempt is being made to support the organ by a bandage. If this is not successful operative measures may be resorted to.—*The Canada Lancet*, January, 1901.

Brain Injury with Peculiar Whistling Spells following Operation.—W. C. Krauss reports the case of a herdsman in a stock yard who was struck by a passing train. He received several scalp wounds and a depressed fracture three inches above and one inch behind the left ear. He was immediately trephined and the depressed bone removed. It was necessary to strap him in bed, as he constantly tried to remove his bandages with his right arm or waved it up and down. About twelve hours after operation he began to whistle, not, however, the "popular songs of the day," but the whistle calls he was accustomed to use in calling or driving his flocks. He would continue whistling for about one minute, then would cease for five or ten minutes, and kept this up at regular intervals until he died, four days after operation. At no time was it possible to distinguish any melody. The sounds were of the same pitch and intensity, and of the same character. They were audible throughout the ward, and attracted the attention of patients and attendants. To the physicians in attendance it was a strange experience to hear these whistle calls coming from a patient in a state of unconsciousness. It was impossible to rouse the patient at any time before or after the operation, and he died, whistling a few minutes before death.—*Journal of Nervous and Mental Disease*, January, 1901.

Treatment of the Umbilical Cord.—Max Stolz describes a simplified method which has given excellent results in the Royal Lying-in Hospital of Graz. The cord is cut twice, the second time being one hour after the first. A fine silk ligature is applied close to the skin and the cord cut through with sterile scissors ½ cm. higher up. A sterile dressing is applied which is changed every second day, and dermatol sprinkled on. This method differs from those of Ahlfeld and Martin in that the application of alcohol and cauterization of the stump, recommended by these two authors respectively, are omitted. Out of five hundred cases it was found that the stump dropped off on an average on the sixth day, while only one instance of secondary bleeding occurred. The advantages of the method are the quickness with which the stump dries up and the minimization of risk of infection by dressing only every other day.—*Wiener klinische Wochenschrift*, January 31, 1901.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 16, 1901:

		Cases.	Deaths.
Smallpox—United States.			
Alabama, Mobile	March 2d to 9th	..	1
California, Los Angeles	February 24th to March 2d	5	
Oakland	February 24th to March 2d	1	
Sacramento	February 24th to March 2d	1	
Illinois, Chicago	March 2d to 9th	7	
Indiana, Evansville	February 24th to March 9th	2	
Kansas, Wichita	March 2d to 9th	23	
Kentucky, Lexington	March 2d to 9th	1	
Louisiana, New Orleans	March 2d to 9th	14	3
Massachusetts, Lowell	March 2d to 9th	1	
Somerville	March 2d to 9th	1	
Michigan, Detroit	March 2d to 9th	1	
Grand Rapids	March 2d to 9th	1	
Minnesota, Minneapolis	February 24th to March 2d	4	
Winona	March 2d to 9th	2	
Nebraska, South Omaha	December 28th to February 5th	5	
N. Hampshire, Manchester	March 2d to 9th	21	
New York, New York	March 2d to 9th	54	10
Ohio, Cincinnati	March 2d to 9th	2	
Cleveland	March 2d to 9th	52	
Dayton	November 2d to 9th	1	
Oregon, Portland	February 1st to 28th	2

SOME FALLACIES OF THERAPEUTICS.[1]

BY GEORGE L. PEABODY, M.D.,

NEW YORK.

IN this day of active therapeutic advance, when the ingenuity of the chemist, the cupidity of the manufacturer, and the honest zeal of the physician conspire to multiply therapeutic agents and procedures, there is danger of our being swamped by the multiplicity of devices to cure the ills of man, if we do not eliminate the useless and the harmful, and leave ourselves unhampered by the vast accumulation of the needless agents of the past and present, with open minds to investigate the claims to recognition of the new arrivals of yesterday, to-day, and to-morrow.

It is astonishing, if we think about it, how prone we are to adopt new procedures, only because they are new, and at the same time, how common it is to perpetuate perfectly impotent and even harmful methods that come to us with no other sanction than that which time can give.

The latest editions of works on therapeutics are full of echoes of the past, repeating the errors and inconsistencies of the old editions and the older writers, from a spirit of conservatism or inertia, as if we had no more accurate means of investigation to-day than our fathers had generations ago. While this may be partly due to the desire of each claimant for literary distinction to write a book as ponderous as the last, it is certainly partly to be explained by an unwillingness or lack of courage to depart from the traditions of the past—a fear of trusting one's individual judgment and experience when the matter under consideration is backed by years of repetition and asseveration, which seem in time to amount to argument and even to conviction.

Take the subject of the use of bitter substances as appetizers as an illustration. Perhaps no idea in therapeutics is more wide-spread or more generally acted upon than that bitter substances conduce to an improvement in the appetite; and certainly none is less susceptible of explanation or of proof. Strychnine salts, the bitterest of them all, are locally irritant to the abraded skin if applied in concentrated solution, and doubtless also to the mucous membrane of the stomach; and if they have any effect in the way of sharpening the appetite after they reach the stomach, this can be explained only by a possible local irritant effect. But they are never put into the stomach in sufficient concentration and quantity to have any such effect; if they were, they would promptly show their toxic powers after absorption. The bitterness, the flavor, the taste of this strychnine is, of course, wasted upon the stomach, which has no sense of taste and no perception of flavor.

Can the operation be explained by its effect upon the sense of taste, or possibly by the stimulation of the saliva, such as is brought about by any object with a pronounced flavor? May it be caused by the swallowing of this saliva itself, which, like any other mild alkali, is known to stimulate the secretion of gastric juice? And may this increased flow of gastric juice announce its readiness for work by calling for food to work upon? If this be the explanation, of course it discredits the use of similar agents in any other form than one which will stimulate the sense of taste and at once proclaims as useless all the methods of administering them in pills or capsules or any similar disguises. It would also suggest the propriety of introducing chewing-gum into the pharmacopœia as a stimulus to the appetite.

It seems to me that, in the vast majority of cases in which bitter substances actually do increase the appetite, they are swallowed with alcohol in some form, perhaps in one of the many seductive combinations known under the name of "cocktail," and that the stimulation of the gastric mucous membrane is really due to the irritant effect of the alcohol rather than to the bitter in the mixture, although that may make it more palatable.

The class of mixtures known as "tonics" and "bitters," which are largely consumed by the laity and to which certainly, in part, is due the idea that bitters are tonics and appetizers, very generally contains a large percentage of alcohol.

A few years ago the Massachusetts State board of health examined many of these, which were procured in the open market. Of forty-seven of those examined, forty-six contained an average of more than twenty-one per cent. of alcohol. This ranks them far above the wines in alcohol percentage, and, indeed, well up among the spirits. One of these was described by its vendors as a purely vegetable extract, "a stimulus to the body, without intoxicating," and it contained over forty-one per cent. of alcohol. Another was called "sulphur bitters," and was advertised to contain no alcohol. It really contained no sulphur, as might have been expected, and it also contained over twenty-one per cent. of alcohol. One dealer's "sherry-wine bitters" yielded forty-seven per cent. of alcohol, and the "stomach bitters" of two other dealers contained respectively forty-two and forty-three per cent. of alcohol.

Almost all of these compounds are sold as being "non-alcoholic," and several of them are boldly recommended as "soothing inducements to temperance," in doses of a wineglassful three "or more" times a day!

It is not surprising that, with these and similar extemporaneously made compounds as the most accessible forms of "bitters," the laity should still believe in the use of bitter substances to provoke an appetite; but is there any real ground for us to add to the arguments in favor of such a belief?

While on the subject of alcohol it may be well to touch upon a very general fallacy in regard to its evil effects upon the body. It happens to me very frequently to get the statement, not only from the patient and his lay friends, but also from his doctor, that he has been most temperate in the use of alcohol, the evidence being that he "never was drunk in his life." Further investigation often shows that he has for years

[1] Read at a meeting of the Practitioners' Society, February 28, 1901.

been a steady and persistent and even a hard drinker, who always drank more alcohol than he could possibly oxidize, whose heart, and arteries, and stomach, and liver, and kidneys, and brain, all show evidences of degenerative changes directly due to alcohol, the victim himself and his friends honestly believing that the limits of temperance have never been overstepped, because he never got drunk. It is not surprising that this should be the lay measure of the possible evils of alcohol, but that doctors should share such a belief, and sanction indulgence in spirits accordingly, is truly deplorable. They should know that the phenomena of intoxication are in themselves incidents of little pathological moment. The heart and the arteries, and the tissues generally, care very little whether their owner gets drunk or not; what they object to is the damaging effect of the alcohol upon them, without any regard to the moral or social consequences of the indulgence.

The fallacy that alcohol adds to body temperature is certainly as old as Shakespeare, who speaks of "hot and rebellious liquors." I suppose, however, it may be said no longer to exist among doctors.

Boric acid occupies a prominent position among the fallacies of therapeutics in the past as in the present, and probably also in the future. It furnishes a capital illustration of the authority of tradition, of the repetition and propagation of error, merely because it has been handed down to us by the fathers; and even if it were an isolated instance, as it is not, it ought to cause us to pause and consider whether we are not today doing much the same thing with many another agent.

From 1702 to 1847,[1] nearly a hundred and fifty years, it was extensively used internally. During much of this time it was supposed to be a potent sedative, and so general and abiding was the faith in its therapeutic power, that it was known as the "sal sedativum." It was then discovered that this appellation of two words contained two vital errors—that it was not a salt but a free acid, and that it possessed no sedative powers whatever. Then, in 1847, Binzwanger experimented with it. He subjected it to carefully conducted tests upon himelf, and came to the conclusion that in therapeutic doses it was a wholly indifferent drug, incapable of accomplishing any useful purpose. It was then for a long time abandoned.

Then later investigation showed that in large amounts, doses of from 7 to 10 gm., it was disturbing to digestion, it caused alkaline vomiting and produced a distinct increase in the amount of urine. It often increased the amount to the extent of two-thirds; and ten minutes after the taking of the first dose, it could be found in the urine.

In 1872 Dumas, a French chemist, discovered its antiseptic power, and soon thereafter it was introduced into surgical practice by Lister. It was taken up by surgeons, as were all of the antiseptics that came to them from Lister, but as compared with carbolic acid it was disappointing in its powers; and it was not long before surgeons condemned it as inefficient and useless, and then its surgical use was largely abandoned.

Presently we came to know that it was less efficient as a means of destroying lower organisms than as a means of preventing their development; but it is only comparatively recently that its true powers and limitations have been ascertained.

A glance at what has been written regarding it,[2] shows that many hold it in high esteem, and that others deny it any merit whatever.

With this difference of opinion regarding it, one is justified in drawing the inference that the causes of the successful use of it by one group and the failure of the other, lie probably not in the drug itself, but in the way in which it is applied.

The first question to be settled with regard to it was this: Does it kill micro-organisms, *i.e.*, has it disinfecting or sterilizing powers? The second question to be settled was: Does it prevent the development of bacteria in the body tissues or in culture media that closely resemble them?

Not to take up your time with all the details of the experiments which were undertaken to settle these points, I may pass on to the conclusions. A saturated solution of the acid was used, cold, a four-per-cent. solution. After thorough exposure to this solution for eight days, staphylococcus was found to be active; and it was necessary to expose this organism to the saturated solution at least three weeks to be sure of killing it. The very sensitive anthrax bacilli resisted an exposure of less than three days.

Thus, the disinfecting power of boric acid is so trifling that for practical purposes in this application it must be disregarded entirely.

If to these organisms, even when they are freely delivered over to it, it does so little harm, it is still less likely to be useful as a means of killing them or similar organisms, when they are buried in the epidermis of a surgeon's hands or concealed on the surface of a wound, when it is simply used as a surgical washing material in its full strength of a four-per-cent. solution. Its disinfecting power in this way is really zero; and in fact it is perfectly possible to infect a fresh wound by washing it with a dirty boric-acid solution. The small amount of the acid left upon the wound by washing it is soon absorbed and disappears, leaving the organisms brought with it to develop unhindered and produce their effects. This has been shown by putting anthrax bacilli into boric-acid solution, and then washing fresh, clean wounds in mice with it. The uniform result is that anthrax is produced in them and kills them.

We are not to conclude that the acid is useless for surgical purposes, however, for, as a means of preventing the development of bacteria with all the consequences of their toxins, it is of decided value. There is a practical difference between killing bacteria and preventing their propagation. In sterile media, if it be present in the strength of four or five per thousand, it prevents the development of staphylococcus; six per thousand prevents streptococcus from growing; nine per thousand, anthrax bacillus; seven per thousand, typhoid bacillus; and three per thousand, cholera spirillum. A much lower per-thousand strength greatly retards the development of all these organisms without wholly preventing it.

In order to see how strong the acid must be to prevent the growth of miscellaneous organisms, such things as are known to be rich in various bacteria were used, like garden earth, water from privies, decomposing blood, etc. With these substances, tubes containing sterilized blood serum and meat extracts were infected, after varying percentages of boric acid had been added to them. Tubes with low percentage, such as one per cent., rapidly showed development of numerous micro-organisms; those that had two per cent. showed a slower development, *i.e.*, not until three weeks had elapsed; while those with two and a quarter, two and a half, and three per cent. remained permanently free from the development of bacteria. Frequent repetition of these experiments led to the same results, so that it would seem fair to conclude that bacteria cannot develop in boric-acid solutions of a strength of two and a half per cent.

The practical application of these conclusions is not difficult, but it does require care. Gauze can be impregnated with strong solutions—up to twenty-five per

[1] Binz: "Vorlesungen über Pharmakologie."
[2] Therapeutische Monatshefte, 1891, p. 477.

cent. in boiling water—and this can be used for keeping wounds sterile.

Thus it is useless as a means of disinfecting wounds, hands, instruments; it is of no use in wounds that have been rendered aseptic by other means, if they can be kept so by proper dressings which exclude air. It is idle to employ it to prevent the development of bacteria in wounds to which bacteria cannot gain access. The chief sphere of its usefulness would be in those wounds which are very likely to contain infecting organisms, such as result from injuries in factories, railways, mines, etc., and also in abscesses, furuncles, ulcers, gangrene, etc.

It often happens in injuries that infecting organisms are forced deeply into tissues where they cannot be reached by strong antiseptics, like sublimate and carbolic acid. These two favorite antiseptics, especially, are much feebler in their bactericidal power below the surface than might be supposed, because of the impairment of their power that results when they come into contact with albuminous substances. If, however, boric acid be applied in potent solution and in such manner as to insure its presence in adequate strength, it will gradually diffuse itself in the tissues and prevent the development of lower organisms, much better than will many other more favorably known agents.

It has been found serviceable in wounds which contain necrotic tissue, which is well known to be a breeding-place of countless bacteria. We may then wait patiently for such tissue to be cast off instead of removing it surgically, with more or less sound tissue.

This agent, which is generally despised by surgeons, really has several advantages over more potent antiseptics. It is non-irritating; it is relatively non-poisonous; it is rapidly eliminated from the body; contact with body tissues does not interfere with its potency.

It is not to be considered wholly harmless. Several cases of severe, and some of fatal, poisoning have been traced to it. Death has resulted from washing out a pleural cavity with a five-per-cent. solution; and a similar result followed the use of the same strength in a large lumbar abscess.

Thus, after a checkered career of two hundred years, boric acid is still under examination and still very differently rated by different observers. While generally rejected by surgeons, the proofs of its power and usefulness seem incontestable; but its earlier uses have entirely disappeared. Almost the only internal use that remains to it is due to its power of acidifying ammoniacal urine in cystitis, if it be taken internally in daily amounts of half a drachm to a drachm.

Tannic acid is another agent whose general use in various ways is much open to criticism. From the harsh, astringent taste, and the styptic feeling, and sense of roughness and stiffness and dryness that it imparts to the mouth, together with a knowledge of its well-known effects upon dead tissues, as seen in tanning leather, the inference has been drawn that, in its application to mucous membranes and to living tissues generally, it causes a contraction of them, of the separate cells and of the blood-vessels, and further, that these effects are due to a coagulation of albumin and abstraction of water from the tissues. These two latter effects are still very generally ascribed to tannin, when it is brought into contact with living tissues.

As a matter of fact, the following is the truth:

From very weak tannin solutions, organic tissues absorb water and swell in consequence; instead of causing a contraction of blood-vessels, in weak and strong solutions alike, it causes arteries, veins, and capillaries to dilate. This dilatation is not due to reflex action as is the case with many irritants, but is a direct effect upon the wall of the vessel. Vessels dilated by tannin can always be again contracted by silver nitrate. On inflamed mucous membranes we can never see any diminution caused by tannin in the lumina of vessels, as can easily be seen under the influence of silver nitrate. Nor can we observe any diminution of existing secretions, in spite of the subjective sensation of dryness that follows its application.

In stomach and intestines it is absorbed and transformed into an alkaline tannate, which no longer precipitates albumin. In this condition it circulates in the blood, only after it has satisfied its chemical affinities and become inert so far as local effects of tannin are concerned. Hence there is no warrant for the very convenient belief that after its absorption it can produce styptic or hæmostatic effects upon remote organs. Thus, we can no longer hope to check bleeding from kidneys or uterus by giving tannin per os. The alkaline tannate in the circulating blood causes no coagulation of albumin, causes no vessel to contract, and would still remain at the site of hemorrhage inert, as it is elsewhere, even granting that it should ever reach the bleeding point. It would seem probably true that the apparent power of a few grains of tannin per os to cause distant hemorrhage to cease, is merely a coincidence, and not an illustration of cause and effect. That serious hemorrhages from stomach, and intestines, and lungs cease without the application of any therapeutic procedure is within the experience of us all. This use of tannin is probably purely a matter of tradition.

Ergot is known to produce a primary fall of blood pressure, which is followed almost at once by an enormous and persistent rise of pressure in the arteries. There is no proof that ergot causes any contraction of pulmonary vessels, and it is known to cause a rise in pressure in the pulmonary artery; yet, in spite of these facts, it is frequently given to arrest pulmonary hemorrhage, and is still recommended for that purpose by some of the best writers on practice.

Lithium is a drug in regard to which much false impression exists, and especially as it occurs in nature in mineral waters. As an experimental solvent for uric acid, Garrod showed the power of lithium carbonate many years ago; clinically, as a solvent in gout, it is almost always valueless when given even in reasonably large amounts. In these amounts it is especially likely to disorder digestion.

Experimental use of it justified great hopes of its clinical value, hopes which practice has not sustained. It certainly has no influence over uric-acid excretion in persons in health.

In mineral waters it is a very frequent ingredient, but it exists always in such minute percentage that as bearers of lithium they must necessarily be valueless. As pure, potable waters many of them have merit, but none of them contain lithium in quantities which ought to entitle them to consideration.

Lithium acetate is less likely to disorder digestion; it is not unpleasant to the taste and is freely soluble. But clinically, like the carbonate, it is of no value.

In regard to arsenic, I have often met a fallacy in the criminal courts, which is fostered by text-books. This is the belief that a toxic dose which causes death must necessarily act as a preservative of the body. Every dissecting-room attendant knows that the amount necessary to preserve a body is much larger than an ordinary lethal dose; and every hospital physician knows that a lethal dose may cause a fatal gastro-enteritis and other degenerative processes in vital organs, and yet may be almost entirely eliminated before death. Bodies so poisoned are especially prone to decomposition, yet I have heard learned advocates inform a jury that death by arsenic could not be asserted, because the body decayed, and because the chemist did not recover from it an amount equal to a lethal dose.

In regard to mercury, therapeutic ideas are especially rich in fallacies. Thus calomel is still given to stimulate the liver, whereas experiment has long since proved it to be a hepatic sedative. That it is at the same time a cholagogue is quite consistent with this, for so is any laxative which acts upon the upper part of the small intestine, and thus causes a discharge of bile that would otherwise be reabsorbed.

The great change in opinion as to the value of mercurialization is of comparatively recent date. Not very long ago it was resorted to in almost every protracted inflammation and fever. Now its field of usefulness is practically restricted to syphilis. It is still somewhat resorted to, improperly as I believe, as a means of removing the products of inflammation of serous membranes, and in some of the organs like the liver and kidneys.

As to the iodides, potassium iodide especially is a willing horse that has often been much overridden. Few drugs have been given so recklessly, to accomplish the most varied purposes, as has potassium iodide. This is to be explained largely by the fact that our ignorance of its physiological action is so great that its utility or uselessness in different conditions can be ascertained only by experience. Furthermore, no amount of knowledge of its physiological effects could explain its utility in syphilis, in the later lesions of which its power is universally acknowledged. Hence we are tempted to "try it" very freely. One of the fields in which it is much misused is arthritis deformans, in which it is wholly without effect. Gout is another. I frequently find it administered with colchicum in the treatment of gout. In serous inflammations it is now less given than it was formerly, but we still encounter it in the treatment of pleurisy, pericarditis, peritonitis, and meningitis. In these diseases it is usually given after the fever has subsided, in the expectation that it will aid in the absorption of exudations, both fluid and plastic exudations. Dispassionate criticism does not reveal a single case of these diseases in which absorption of exudation is caused by the iodides. To remove hyperplastic connective-tissue growths in certain viscera, it is still employed, without the slightest warrant. Thus it is often blindly given in chronic nephritis, cirrhosis, and meningitis. Except in syphilitic diseases of these organs, it is wholly without effect.

Its utility in asthma probably accounts for a certain faith in its utility in emphysema. Except that the potassium element in it may lower arterial tension by its direct effect upon an overacting heart, there is no reason for its use in this latter condition.

In chronic lead poisoning there is a general belief that potassium iodide aids in the elimination of lead which has been deposited in the tissues. Now lead is chiefly eliminated by the intestines; and there is absolutely no proof that the iodide increases the activity of the elimination of lead in any way. Still the text-books go on repeating the injunction to give iodide in these cases, in the hope of causing elimination of lead by the urine, which has been shown by painstaking investigation not to occur.[1] Iodide baths are now rarely resorted to. They were formerly much in vogue in spite of the fact that absorption of it by the skin to any appreciable extent has never been proved.

Many mineral waters are praised because of the iodine which they contain. When it is present at all in them, it is always in too minute a proportion to be significant.

It is gravely asserted that the iodine in sea air contributes much to the beneficial effects of a residence by the sea.

Who among us did not at one time believe in the efficacy of the Bergeon method of treating pulmonary tuberculosis? Which of us had not at one time a means of relieving dyspnœa in quebracho? And who resorts to these methods now?

Of all the hundreds of doctors who give creosote and its allies internally in tuberculosis, are there not many who believe that its beneficial effects are due to its antagonism to the bacilli? And yet there are positive proofs that it never exerts its curative influence by the manifestation of any such power; but only by improving intestinal digestion, and thus benefiting nutrition.

Among present-day fallacies perhaps none are more to be regretted than several of those that relate to gaseous or aërial disinfection. Sulphurous acid gas, chlorine, and other gases are very unsafe substitutes for cleanliness and scrubbing with antiseptics or even rubbing the bounding surfaces of a room with bread. Most of the gaseous substances employed have so little penetrating power that they will not destroy animal life on the other side of a thin board partition. Formaldehyde is probably the best of them, but its penetrating power is feeble as compared with superheated steam. Of course, there is no special advantage in disinfecting the air of a room at all, for it may all be removed by opening doors and windows: it is the other contents and the bounding surfaces which need our attention.

The idea of disinfecting a room by the generation of chlorine gas in it while it is occupied by human beings is still advocated by some as practical, absurd as it seems to be.

The inhalation of oxygen is often practised, upon very absurd premises. The amount of oxygen which is taken up by the blood in the lungs is wholly dependent upon the consumption of oxygen in the systemic circulation and upon the hæmoglobin percentage in the blood cells. Granted that there is no obstruction to the entrance of air to the lungs, venous blood is transformed into arterial blood in the lung capillaries just as easily, and as quickly, and as fully if atmospheric air be inhaled as if pure oxygen be substituted for it.

When obstruction of any sort exists, or when anything interferes with the normal atmospheric pressure in the air passages, oxygen inhalations will give great relief to the dyspnœa which ensues. Thus, for example, in balloon ascensions where the atmosphere is markedly attenuated, symptoms of oxygen insufficiency are known to occur and can be relieved by breathing a more richly oxygenized air, without altering the atmospheric attenuation.

In certain diseases of the respiratory organs a similar condition comes about, and in these conditions oxygen often relieves symptoms of dyspnœa, and remedies the defective exchange of gases in the lungs and the consequent accumulation of carbonic acid in the blood. Among such conditions are acute exacerbations of chronic bronchitis, emphysema, asthma, some bad cases of pneumonia, miliary tuberculosis with its intense bronchitis, and some cases of heart disease. But there is no justification for the extensive use of oxygen in general diseases which either arise from defective hæmatosis or are connected with imperfect digestion or oxidation; such as chlorosis, anæmia, leukæmia, gout, uric-acid diathesis, scurvy, rickets, etc.

In these cases the amount of oxygen absorbed is wholly dependent upon the percentage of hæmoglobin in the blood, and cannot be increased at will by increasing the oxygen percentage in the air that is breathed.

The sphere of usefulness of oxygen inhalation under normal atmospheric pressure is really very limited. As a matter of fact, arterial blood is more than nine-tenths saturated with oxygen by the breathing of atmospheric air; and if we could increase this amount by let-

[1] Therapeutische Monatshefte, 1893, p. 476.

ting a patient breathe pure oxygen, it would not benefit him. The arterial blood would still yield only its normal oxygen percentage in the system, and, as venous blood in the right heart, be a little richer in oxygen than is normal—that is all.

The length of this paper has gone beyond the limits which I had intended to set for it; but I have merely selected for your consideration a few of the many topics which crowd upon one's mind when he contemplates its title. That I might have made it much longer will perhaps induce you to excuse its length.

IONIZATION IN ITS PHYSIOLOGICAL AND PATHOLOGICAL RELATIONS.

By MARTIN H. FISCHER,

PATHOLOGICAL LABORATORY, RUSH MEDICAL COLLEGE, CHICAGO.

I. The Theory of Electrolytic Dissociation.—Precipitation membranes, permeable to water but impermeable to some substances dissolved in the water, were discovered by Moritz Traube, but it was not until Pfeffer[1] conceived the idea of supporting these delicate membranes in the walls of unglazed vessels of earthenware that accurate osmotic measurements could be made with them. This end he accomplished by placing one of the membrane-forming solutions (copper sulphate) on the inside of the porous vessel, and the other (potassium ferrocyanide) on the outside. The two solutions, penetrating the wall from opposite directions, meet in the interior of the wall, and there deposit a semi-permeable film (copper ferrocyanide). The porous vessel is then filled with aqueous solutions of various substances (sugars, salts, etc.) and immersed in pure water. A current of water passes from without into the cup containing the dissolved substance, with a force to which Pfeffer applied the term "osmotic pressure." With a suitable manometer the osmotic pressure may be measured directly. The pressure of a given solution is very nearly proportional to its concentration, in other words, proportional to the number of molecules it contains. With an increase in temperature, there is an increase in the osmotic pressure.

Previous to the experiments of Pfeffer it had been known that certain vegetable cells burst when placed in pure water or in a solution of less concentration than that contained in the cell. Pfeffer pointed out that in this case there is a semi-permeable membrane (the cell wall) separating the cell contents from a liquid of lower osmotic pressure, and that the rupture of these vegetable cells is due to an imbibition of water, with consequent rise in cell turgor.

The experiments of Pfeffer paved the way for van't Hoff's[2] theory of dilute solutions, which shows the complete analogy between dilute solutions and gases. The semi-permeable membrane furnishes a means of directly measuring the osmotic pressure of a solution. It is found that the osmotic pressure exerted by a dissolved substance is the same as the pressure exerted by an equal amount of that substance volatilized and occupying the same volume as that of the solution. Pfeffer's results show that the osmotic pressure at constant temperature is proportional to the concentration of the solution, or, in other words, the osmotic pressure of a given quantity of substance is inversely proportional to the volume of the solution which contains it. Other experiments show a close relation existing between the absolute temperature of a given solution and its osmotic pressure. These facts permitted van't Hoff to apply the gas laws of Boyle and Gay-Lussac to dilute solutions: At constant temperature the pressure of a dissolved substance varies inversely as the volume of the solution; at constant volume the osmotic pressure is proportional to the absolute temperature.

When Avogadro first published his law—equal volumes of different gases under the same physical conditions contain the same number of molecules—a number of facts were found which seemed not in accord with it. It was observed, for example, that the vapor density of ammonium chloride—and hence its molecular weight determined from its vapor density—was only half (while its vapor tension was twice) as great as was required by its formula, NH_4Cl. The explanation of this apparent exception was forthcoming, however, when it was shown that upon being heated ammonium chloride splits up into ammonia and hydrochloric acid, thus doubling the number of molecules. It is a similar dissociation that accounts for the diminished density and increased tension of the vapors of other substances which show like exceptions to the law of Avogadro.

Van't Hoff's application of the law of Avogadro to dilute solutions gives us: Equal volumes of all solutions having the same temperature and the same osmotic pressure contain the same number of molecules. The law of van't Hoff had to contend with the same difficulties as that of Avogadro; for, while the behavior of many solutions went to support it, that of others offered apparent exceptions to the rule. The experiments of Pfeffer show that the osmotic pressure of a solution is proportional to the number of molecules it contains. Other facts go to show that the rise of the boiling-point (diminution in vapor tension), or the lowering of the freezing-point, of a solution is also dependent upon the number of dissolved molecules. Now, for many solutions, more especially strong acids, bases, and salts, it was found that the osmotic pressure is higher than the law of van't Hoff requires. Similarly, it was found that these same substances show too great a rise of the boiling-point, and too great a lowering of the freezing-point. In other words, they conduct themselves as though they contain a larger number of molecules than is expected from the chemical formulæ of the dissolved substances.

To explain these exceptions recourse must be had to one of two theories; either the law is not an absolute one, or else some change has occurred in the solutions. While working on the electrical conductivity of various solutions, Arrhenius[3] noted that those which conduct electricity are those which offer apparent exceptions to the law of van't Hoff. It was this fact which led him to the conclusion that in solutions which are conductors of electricity (electrolytes) the molecules of the dissolved substance are, in some way, dissociated into simpler substances—the ions. An electrolyte in solution is converted, either wholly or in part, into ions, each of which conducts itself like a molecule. This splitting up of molecules into ions makes the osmotic pressure greater, the boiling-point higher, and the freezing-point lower than required by the molecular formula of the electrolyte, and, to a degree, dependent upon the amount of dissociation. According to Arrhenius' theory of electrolytic dissociation, then, a solution of hydrochloric acid is made up of H- ions, Cl- ions, and undissociated molecules of HCl. Similarly, a solution of sodium hydroxide is made up of Na- ions, OH- ions, and undissociated NaOH. The degree of dissociation is dependent upon the degree of dilution—the greater the dilution, the greater the number of dissociated molecules. The greater the degree of dissociation, the greater is the electrical conductivity.

Kohlrausch ascertained experimentally that the molecular conductivity * of a salt increases as the dilution increases, and that the rate of increase becomes

* By the molecular conductivity of a solution is meant its specific conductivity, multiplied by the volume of the solution in litres which contains one gram-molecule of the dissolved substance.

smaller as the dilution increases, until finally a point is reached at which the molecular conductivity remains constant, even though the addition of water to the solution is continued. At this point, dissociation is complete. For many substances, more especially strong acids, bases, and their salts, dissociation is practically complete when a gram-molecule * is dissolved in 1,000 litres of water. Solutions which conduct electricity freely are entirely split up into ions, while those which conduct electricity but poorly are dissociated to but a small extent. Upon this hypothesis Arrhenius measures the degree of dissociation of a substance by the conductivity of its solutions.

Ions differ from molecules, in that they are charged with positive or negative electricity, and to this saturation with electricity is due the difference in the behavior of the molecules and ions. The negatively charged ions which travel toward the positive pole or anode are termed anions; those charged with positive electricity and travelling toward the negative pole or cathode are termed cathions. Thus the ions of a completely dissociated hydrochloric acid solution may be written H^+ and Cl^-. In solution the positive and negative ions neutralize each other, and so the electrical equilibrium of the solution is maintained.

Beside the facts already brought forth, numerous other evidences (specific volume, optical and thermal properties of solutions, etc.) go to prove the truth of the dissociation theory of Arrhenius. The properties of the aqueous solutions of electrolytes are, then, well explained by the assumption that in these solutions the dissolved substances are split up into ions, and that the properties of the solutions are due to the properties of the ions contained in them. For example: Hydrochloric acid dissociates into H- ions and Cl- ions. Sodium chloride dissociates into Na- ions and Cl- ions. These solutions are the same in so far as they both contain Cl- ions, and different because one contains H- ions and the other Na- ions. These differences determine the differences in the properties of the two solutions.

II. The Relation of Ions to Life Phenomena.—(1) In 1896, Kahlenberg and True[4] made the first application of the theory of electrolytic dissociation to the problems of physiology. The physiological action of any substance is due to its chemical character. The chemical character of the solution of an electrolyte is due to the properties of its ions, plus the properties of its undissociated molecules; hence these authors concluded that the physiological effects of such a solution must also be due to the ions and to the undissociated molecules contained in it. Kahlenberg and True experimented upon the bean *Lupinus albus* L., to determine in how strong solutions of various acids, bases, and salts the roots will keep alive. Freshly germinated seeds, properly supported on corks, were placed in the solutions to be tested. Failure of growth and certain changes in the appearance of the radicles served as evidences of the death of the lupine. For strong acids, HBr, HCl, HNO_3, H_2SO_4, etc., the point at which the seedlings will just live is reached when a gram-molecule is dissolved in 6,400 litres of water. In solutions as dilute as this, dissociation into ions is complete, and there are no longer present any molecules of the acid. Hence the toxic action cannot be due to the molecules. If it can be proved that at this dilution the anions are non-toxic, the conclusion seems justified that the poisonous properties of these acids are due to their H- ions.

No toxic effect is exhibited by a solution of NaCl equimolecular * with an HCl solution that produces the death of a lupine, nor even by one of greater concentration. At the dilution used both these substances are totally dissociated. The solutions are the same in so far as they both contain Cl- ions, and different in that one contains H- and the other Na- ions. The toxicity of HCl cannot be due to the Cl- ions, as an equal, or even larger, amount of the same ions in an NaCl solution proves harmless. The Na- ions, can have no toxic action, since the NaCl solution is non-toxic. The toxic action of the HCl must then be due to the H- ions. The same reasoning can be applied to $NaNO_3$ and HNO_3, and to the other acids mentioned above.

Similarly, the toxic effects of the hydroxides are due to their OH- ions. NaCl produces no effect upon lupines in solutions equimolecular with toxic solutions of NaOH. It has already been shown that at the great dilution at which these solutions are toxic neither the Na- ions nor the Cl- ions are the toxic agents. The action of the NaOH must then, of necessity, be due to the OH- ions. That it is the ionic condition of the H and OH which determines the toxicity is proved by the fact that in H_2O, in which these constituents exist in practically an undissociated state, none is exhibited.

The poisonous properties of a dilute solution are, therefore, due to the ions it contains, and if at the particular concentration under consideration toxic ions of only one kind are present, the behavior of the solution is to be attributed to those ions.

(2) Loeb[5] used the change in the irritability of the gastrocnemius muscle of a frog, and the amount of water absorbed by it, as an index of the toxicity of the solution of an electrolyte in which the muscle was immersed. A muscle immersed in a physiological (0.7 per-cent.) NaCl solution † shows, during the first hour, no variation in weight. If, however, a small quantity of an inorganic acid or of an alkali be added to the solution, there is a great increase in the weight of the muscle. For inorganic acids the increase varies with the number of H- ions in solution. Equal amounts of H- ions, in equal amounts of the solvent, induce quantitatively equal increase in weight. A muscle immersed in a physiological salt solution to which a small amount of the hydroxide of lithium, sodium, potassium, strontium, or barium has been added, shows an increase in weight, due to the OH- ions in solution. For equal amounts of OH- ions in equal amounts of the solvent, the weight increase is equal.

The increase in the weight of the muscle is due to an absorption of water, explainable on the ground that the H- ions of the acids, or the OH- ions of the alkalies have a fermentative action which causes hydrolytic splittings in the muscle, and an increase in its osmotic pressure.

Loeb[6] also investigated the influence of organic

* A gram-molecule contains the weight of one atom or one molecule of the active chemical, expressed in grams. A gram-molecular solution contains in a litre the weight of one atom or one molecule of the active chemical expressed in grams. Taking the molecular weight of hydrochloric acid as 36.4, a gram-molecule contains 36.4 grams. A gram-molecular hydrochloric solution contains 36.4 grams of the pure acid, diluted to make one litre, 1,000 c.c., at 0° C.

* Comparative studies of the physiological action of electrolytes have usually been made with percentage solutions. In dealing with the properties of acids, bases, and salts, we must compare equimolecular (chemically equivalent) solutions. A normal HCl solution contains 36.4 grams of the acid; a normal HBr solution contains 80.9 grams of HBr. The amount of H contained in each of these solutions is, however, the same. Similarly, a normal NaCl solution contains 58.5 grams of the salt. Compared with a normal HCl solution, the Cl concentration is the same in both solutions. Thus, chemically equivalent quantities of different substances can be compared. A failure to compare chemically equivalent solutions accounts for the erroneous results which have been obtained whenever comparative studies have been made on the physiological, pathological, and pharmacological action of chemical compounds.

† A 0.7 per-cent. NaCl solution is supposed to have the same osmotic pressure as the tissue fluids. For this reason a muscle immersed therein neither loses nor takes up water.

acids upon the absorption of water by muscles, and in a large series of acids found that the degree of dissociation of the acid in solution, and the amount of water absorbed by the immersed muscle, bore no relation to each other.

Although a muscle immersed in a 0.7 per-cent. NaCl solution shows no increase in weight during the first hour, a considerable increase is not uncommon after several hours. After eighteen hours, an increase of nearly seven per cent. was noted by Loeb. When a gastrocnemius is immersed in a 2.8 per-cent. NaCl solution it loses water. Later, however, this is followed by an absorption of water and an increase in weight, which exceeds the original weight of the muscle. In his first communication, Loeb suggested as a possible explanation for these apparent exceptions to the laws of osmotic pressure, the occurrence of secondary changes in the muscle, accompanied by an increase in the number of molecules. Such an increase would be accompanied by a rise of osmotic pressure within the muscle. In a series of experiments in which the gastrocnemii of frogs were immersed in a 4.9 per-cent. NaCl solution, the reaction of the muscles, in all cases, became distinctly acid after a few hours. The time required for such a change increased with the dilution. Dry-weight determinations showed the increased weight to be due to an absorption of water, and not to an increase in the amount of NaCl in the muscle. Thus Loeb proved the truth of his original hypothesis, and showed that the weight increase in a muscle immersed in a pure salt solution is due to secondary changes associated with acid formation. These observations of Loeb throw light upon several points in muscle physiology. Ranke[7] has shown that a fatigued muscle absorbs water from the blood. Other observations have shown that a stimulated muscle becomes distinctly acid in reaction. These facts harmonize well when we remember that the presence of an acid in a muscle increases its osmotic pressure, and causes it to absorb water even from a 0.7 per-cent. salt solution.

Immersion in hypotonic * solutions is also accompanied by acid changes, an increase in the osmotic pressure of the muscle cells, and a consequent absorption of water and increase in weight. To show the far-reaching importance which these phenomena have in physiological questions, I quote directly from Loeb:

"We know that during muscle activity acid is formed, and furthermore, that an active muscle absorbs water. . . . In this water absorption is to be found the cause of labor hypertrophy. The possibility of determining the amount of katabolic change during muscular activity, from the increase in osmotic pressure, lies near at hand. It is to be remembered, however, that it is this very katabolic change which leads to the formation of acids, and to an increase in the osmotic pressure of the muscle during activity. This rise in osmotic pressure is caused, in the main, by the fermentative power of the H- ions of these acids. Acid production is, then, of significance in the production of labor hypertrophy. It would be of interest to know if acid formation does not underlie in animals, as in plants, all phenomena of growth.

"From these experiments we also get an insight into the ways and means by which an organism protects itself against a loss of water, or adapts itself to conditions in which water famine prevails. Biology has thus far had an eye only for the means of protection against evaporation. Our experiments show, however, that a second group of protective measures present themselves which are of service to the organism, namely, increase in osmotic pressure. We have seen that loss of water is in itself accompanied by acid formation, and that, in consequence, a muscle is put in a position to draw water even from a concentrated solution. It seems possible that the wonderful power which some plants possess to adapt themselves to a 'dry' earth, and their power to draw water from the same is dependent, in part at least, upon processes of the above kind. It might, perhaps, be of interest to determine if, during great dearth, an increase in osmotic pressure does not occur, dependent upon the formation of acids in such plants."

(3) It is a well-known fact that water combines with sodium, potassium, and calcium soaps in definite proportions; but that the amount of water absorbed by the soaps is dependent upon the metal involved. The potassium soaps absorb a large amount of water. The sodium soaps absorb much less, but still a large amount. The calcium soaps, on the other hand, take up but little water. Substitution of sodium for potassium in potassium soaps is accompanied by a loss of water; substitution of potassium for sodium in sodium soaps is accompanied by the absorption of water.

In a series of experiments, Loeb[8] demonstrated the similarity which exists between the absorption of water by soaps, and the absorption of water by muscles. Previously this author found that a muscle immersed in a 0.7 per-cent. NaCl solution suffers neither increase nor decrease in weight during the first hour of immersion. Slight variations were noted, however, during the first hour, when isotonic solutions of potassium, calcium, or lithium were used. After eighteen hours these variations become considerable. In a NaCl solution the muscle has gained seven per cent.; in KCl there is an increase of forty to fifty per cent.; in $CaCl_2$ a loss of twenty per cent.; in LiCl an increase of a few per cent. Equimolecular solutions of the chlorides of strontium, barium, cobalt, and manganese affect the muscles as do solutions of calcium chloride.

As the degree of dissociation of sodium and potassium salts is about the same, it is clear that the above variations in the absorption of water cannot be dependent upon differences in osmotic pressure. The addition of a KCl solution to a sodium soap is accompanied by a diffusion of K- ions, a substitution of the K- ions for the Na- ions, and the formation of a potassium soap. An absorption of water occurs with the formation of the potassium soap. Similarly, the addition of a $CaCl_2$ solution to a sodium soap is accompanied by a diffusion of Ca- ions, the formation of a calcium soap and a consequent loss of water. Loeb believes that similar conditions prevail in the case of muscle. The various salt ions stand in definite combination with the proteids of the muscle. Immersion of a muscle in a given solution is accompanied by a diffusion of Li-, Na-, K-, or Ca- ions. In the case of soaps such a diffusion of ions would result in the formation of lithium, sodium, potassium, or calcium soaps. In the case of muscles a similar reaction occurs and compounds between the metal ions and the proteids of the tissues are formed. These lithium, sodium, potassium, and calcium ion proteid compounds resemble the soaps in their relative affinities for water.

(4) In 1881 Biedermann[9] discovered that striped muscle fibres contract rhythmically when immersed in solutions of various sodium salts, but it was not until 1899 that Loeb[10] showed that this phenomenon is dependent upon the presence in the solutions of certain ions. A series of experiments was made to determine the behavior of the frog's gastrocnemius in various salt solutions. As a result of these observations it was found that rhythmic contractions occur only in solutions of electrolytes, and not at all in solutions or non-conductors (urea, glycerin, dextrose, cane sugar,

* When two solutions have the same osmotic pressure, they are said to be isotonic. When the osmotic pressure is unequal, the one with the higher pressure is hypertonic; that with the lower pressure is hypotonic.

milk sugar). Herein lies another proof of the existence of ion proteid compounds. Solutions of all sodium salts are capable of calling forth rhythmical contractions in skeletal muscles, but in a 0.7-per cent. NaCl solution contractions begin later and are less powerful than in an equimolecular NaBr solution. This indicates that not only the metal ions, but also the anions, influence the physical properties of the ion proteids. The use of other solutions showed that Li-, I-, and F- ions are also capable of inducing rhythmic contractility in muscle, but that the character of the contractions varies greatly, and is dependent upon the specific action of the different ions.

Solutions of sodium salts produce rhythmic contractions of skeletal muscles only when the muscle cells contain a sufficient number of Ca- ions. As soon as there is a lack of Ca- ions, the Na- ions lose their power. On the other hand, if an excess of Ca- ions is present—produced experimentally by adding $CaCl_2$ to the NaCl solution—no contractions result. It looks, therefore, as if the substitution of certain quantities of Na- ions for Ca- ions causes contractions, but if this substitution is carried too far the muscle loses its irritability. On the other hand, the presence of too many Ca- ions in the NaCl solution prevents the substitution of a sufficient number of Na- ions for the Ca- ions, and so rhythmical contractions are prevented. Other ions (K, Mg, Bi, Ba, Sr, Co, Mn, etc.) retard or prevent the occurrence of rhythmic contractions in skeletal muscles. It is the Ca- and K- ions in the blood which prevent the skeletal muscles of our bodies from beating rhythmically.

That the retarding action of the Ca- and K- ions is not dependent upon the reduction of the irritability of the muscle is proved by the fact that in a 0.7 per-cent. NaCl solution to which has been added an amount of $CaCl_2$ sufficient to prevent rhythmic contractions, the irritability of the muscle suffers less and is preserved for a longer time than in a pure physiological salt solution. The loss of contractility seems rather to depend upon the formation of definite proteid compounds with Ca- and K- ions.

The presence of small quantities of H- and OH- ions favors the production of rhythmic contractions when present in solutions of electrolytes which are in themselves capable of calling them forth. In solutions of non-conductors, or in solutions of electrolytes which have a retarding influence upon the occurrence of rhythmic contractions, the addition of small amounts of NaOH, HNO_3, etc., exerts no such favorable influence. To OH- and H- ions, then, is to be attributed a katalytic action which, though capable of aiding, is, in itself, incapable of calling forth rhythmic contractions.

When the spinal cord or the nerve connected with the muscle is immersed in solutions of electrolytes capable of calling forth rhythmic contractions in muscle, no such contractions result. This proves that the rhythmic contractility of a muscle is inherent in the muscle tissue itself, and not in the nerves connected with it.

Coupling his results with those of Greene,[11] who previously had determined the relation of the inorganic salts of the blood to the automatic activity of the terrapin heart, Loeb concluded that the same factors which determine the production of rhythmic contractility in the gastrocnemius of a frog are those which determine the automaticity of the heart. This view is confirmed by the experiments of Lingle[30] on the automatic activity of the turtle heart.

More recently, Loeb[12] has studied the effect of ions upon the rhythmic contractility of a medusa—Gonionemus. The Gonionemus is a jellyfish consisting of a rhythmically contracting swimming bell with a peripherally grouped chain of ganglia. The experiments of Loeb demonstrate that Na-, K-, and Ca- ions exist in definite but different proportions in the contracting bell, and in the peripheral chain of ganglia. Both myogenic and neurogenic contractions occur. The former are those originating from the bell when freed from its ganglia; the latter those originating from the peripheral ganglia. The myogenic contractions are prevented by a smaller amount of K- and Ca- ions in the surrounding NaCl solution than are the neurogenic contractions.

(5) Other facts go to prove the truth of the existence of ion proteid compounds. If the foregoing is correct it follows that we may regard protoplasm as a proteid in combination with various ions. To represent this idea graphically the formula of an ion proteid compound might be written thus:

Such a compound would have definite chemical characteristics. Let us suppose that it were possible to substitute Na- ions for K- ions in the above formula, thus:

It is evident that the latter ion proteid compound would differ chemically and physically from the first. Theoretically these two proteids should differ physiologically.

If it be true that certain life phenomena depend upon the presence of proteids combined with certain metal ions (Na, K, Ca, Mg, etc.), then it follows that solutions which supply the organism with only one sort of ions must alter the chemical and physical properties of the proteids and so be poisonous. On this ground Loeb[13] came to the conclusion that even a NaCl solution must be poisonous, although this salt permeates all animal tissues, and is the main constituent of sea water.

Howell[14] has attributed to the NaCl in our blood the rôle of preventing the tissues from losing or taking up water, that is to say, the property of maintaining the osmotic equilibrium. Solutions of NaCl in concentrations of 0.5–1 per cent. have ever been held to be "indifferent" substances. Thus it has been believed that such solutions may be left indefinitely in contact with muscle preparations, without affecting their irritability. Locke,[15] however, found that differences existed between the contraction curves of muscles immersed for some time in NaCl solutions, and those kept in a moist chamber or tested immediately after removal from the body of an animal. On this ground he concluded that NaCl is not an "indifferent" substance in animal physiology. True[16] noted that the osmotic pressure of solutions of $NaNO_3$ and KNO_3 in which Spirogyra will just live, is lower than that of a pure sugar solution; hence he concluded that other factors than disturbances in osmotic equilibrium go to make these salts harmful for Spirogyra.

Loeb used in his experiments the freshly hatched fundulus, a marine fish. An addition of five per cent. NaCl to sea water does not injure this animal. In a pure NaCl solution, isotonic with sea water, the fish dies, however, in a short time. When such a NaCl solution is diluted with distilled water, the fish lives longer the greater the dilution, and in pure distilled water lives indefinitely.

Thus is demonstrated the toxic effect of NaCl in pure solution. It now becomes necessary to show that the addition of certain other ions annihilates the toxic effects of NaCl. If small amounts of solutions of KCl, $MgCl_2$, and $CaCl_2$ are added to the NaCl solution, the poisonous effects of the pure NaCl solution disappear, and the fish lives indefinitely. Indeed, the

addition of small amounts of K- and Ca- ions counteracts the toxic effects of NaCl, even in solutions hypertonic with sea water.

The Gonionemus propels itself by rhythmical contractions of its swimming-bell. When thrown into a pure NaCl solution the rhythmical contractions cease; when returned to sea water the contractions of the bell recommence. In the pure NaCl solution the Na- ions take the place of the K- and Ca- ions; this alters the physical properties of the tissues and prevents the occurrence of contractions. The return to sea water is accompanied by the replacement of K- and Ca- ions in the ion proteid compounds, and a consequent return of contractility. A dilute solution of NaCl permits this medusa to contract much longer than one isotonic with sea water. The addition of KCl, $MgCl_2$, and $CaCl_2$ counteracts the poisonous effects of a pure NaCl solution. Thus it is again proved that the Na- ions in a pure NaCl solution are poisonous, but that the same solution is harmless if K- and Ca- ions are present. What is true in these experiments of the toxicity of a pure NaCl solution is equally true of the toxic properties of a pure KCl, $CaCl_2$ or $MgCl_2$ solution.

The relation of the activity of the cilia of sea-urchin larvæ to the salts of the sea water was studied by Loeb. The slowly poisonous effect of a pure NaCl solution is counteracted by the addition of small amounts of K- and Ca- ions. During these experiments the remarkable fact was brought out that ciliary motion continues for some hours in solutions of $MgCl_2$ and $CaCl_2$, and in solutions of NaCl and KCl—both of them liquids in which muscular contractions are impossible. This proves conclusively that ciliary motion is not, as is often believed, a muscular phenomenon.

A study of the effects of ions upon young trout and tadpoles has led Anne Moore[23] to practically the same conclusions as have been reached by Loeb in regard to the poisonous effects of a pure NaCl solution.

Recently Loeb[12] has studied the poisonous effects of the various ions upon embryonic tissues.

(6) Entirely independently of Loeb, Pauli[17], [18] has reached the conclusion that the inorganic salts of the animal economy exist in combination with the protoplasm as ion proteid compounds. The coagulation of albumin by heat occurs only in the presence of certain neutral salts. With variations in the amount of salt, variations occur in the temperature at which the albumin coagulates. It is found that certain laws govern the point at which a given salt-albumin mixture will coagulate. When the effects of equimolecular salt solutions on the temperature of coagulation are compared, and the results arranged according to the different acidulous radicles, it is found that the action of the salts is independent of the bases. On the other hand, arrangement according to the basilous radicles shows the action of the salts to be independent of the acidulous radicles. The effect of a given salt upon the coagulation of albumin is, then, not dependent upon either its basic or acid constituents alone, but upon the sum of the action of its constituent ions. The metallic ions, arranged in the order of their ability to raise the point of coagulation of albumin, run as follows: NH_4, K, Na, Li, Ba, Mg. The acid ions arranged in the same way show: Chlorides, acetates, sulphates, oxalates, chromates, chlorates, nitrates, bromides, and iodides.

A study of the effect of the mixture of two salts containing a common ion, with a solution of albumin, shows that there exist certain mixtures of two such salts in which the addition of more salt of the one kind produces no change in the point of coagulation of the albumin. The occurrence of such stable salt-albumin compounds are explainable on no other ground than that the albumin molecule exists in actual combination with both the ions of a given salt.

A further proof of the correctness of this view lies in the solubility of globulin. Globulin (egg) is soluble in neutral salt solutions of moderate concentration. Diluting to a certain point with water results in a precipitation of the globulin. Similarly, the addition of neutral salts to the original globulin solution causes its precipitation. Changes, then, in the salt concentration (changes in the ion concentration) bring about changes in the properties of the globulin. According to Pauli, the increase in the concentration of the neutral salt solution diminishes its electrolytic dissociation, and with the consequent decrease in the number of free ions a precipitation of the globulin occurs. Comparative studies with the substitution of equimolecular solutions of non-electrolytes (urea, dextrose) for the salt solutions show that the solubility of globulin is dependent upon the presence of free ions.

* * *

The question has often arisen, What is meant when we say that a muscle-nerve preparation or a living tissue possesses a positive or negative charge of electricity? As the result of certain experiments on the influence of static electricity upon nerve-muscle preparations, Loeb[19] has suggested the following: Applying the law of electrical conductivity in solutions to conductivity in living tissue, it is seen that the conductivity is dependent upon a migration of ions, as it is only the liquid portion of a cell which can serve as a conductor. According to Ostwald, the passage of static electricity in a liquid conductor can be conceived of only as the passage of positive or negative ions over the surface of the solution. In a similar manner, Loeb conceives of a distribution of negative or positive ions upon the surface of a nerve-muscle preparation. The passage of a spark between the two metal spheres of the discharger of the static machine causes a migration of ions in the muscle, accompanied by the transformation of ions into atoms. These, directly or indirectly, produce the chemical changes which in the muscle manifest themselves in contractions at the time of the electrical discharge.

* * *

In 1897 Richards[20] expressed the view that the sour taste of acids is dependent upon the H- ions which they contain, and suggested the possibility of using the intensity of the taste as a means of measuring the amount of their electrolytic dissociation. Experiments with a series of mineral acids showed that a definite relation exists between the concentration of the H- ions in the solution and its power to affect the sense of taste. As a further proof of the fact that it is the H- ions which determine the degree of acidity in the solution of an acid, the following experiment may be cited: To an HCl solution of known strength was added equimolecular NaOH in various quantities. It was found that the degree of acidity decreases as the amount of NaOH increases. When enough NaOH is added to neutralize completely the acid, the sour taste of the solution is entirely lost. The explanation for this change is a simple one. The chemical reaction which occurs may be thus expressed:

$$HCl + NaOH = NaCl + H_2O$$

The H- ions of the HCl have combined with the OH- ions of the NaOH to form H_2O. H_2O is practically undissociated, hence no free H- ions are found in the resulting solution. Since there are no H- ions in this solution, it has no sour taste. When only partial neutralization occurs a sour taste persists, proportionate to the number of H- ions left in solution.

In 1898 Kahlenberg[21] repeated and enlarged upon the experiments of Richards. Kahlenberg's experiments led him to formulate the general law: The taste

of the solution of an electrolyte is dependent upon the ions contained in it.

The sour taste of acid solutions is due to the H- ions contained in them. The H- ion can be detected in $\frac{n}{800}$* solutions, though under $\frac{n}{2000}$ the taste is not sour, but astringent in character. Richards was able to detect the H- ion in $\frac{n}{10000}$ solutions. The OH- ion produces an alkaline taste detectable even in $\frac{n}{4000}$ solutions. The halogens have a salty taste. Of them the Cl- ion has the most pronounced taste, and is recognizable in $\frac{n}{50}$ solutions. The Cl- ion affects the sense of taste at a slightly greater dilution than the Br- ion, while the I- ion is not recognizable except at a concentration above a $\frac{n}{6}$ solution. The ClO_3- and BrO_3- ions have a salty taste, but this is not so pronounced as in the case of the Cl- and Br- ions. The NO_3-, SO_4-, and CH_3COO- ions have all only a slight taste. The last-named is slightly sweetish.

Na- ions are slightly disagreeable to the taste. K- ions produce a peculiar, bitter, disagreeable taste which is much more pronounced than that of the Na- ions. The taste of Li- ions simulates that of the Na- ions, but is less marked. Mg- ions have a distinctly bitter taste in $\frac{n}{6}$ solutions. NH_4- ions also have a bitter taste. The taste of Ag- and Hg- ions is metallic in character, and is detectable in the first in concentrations above a $\frac{n}{50000}$, and in the second in concentrations above a $\frac{n}{20000}$ solution.

The intensity of the salty taste of Cl-, Br-, and I- ions decreases with an increase in their atomic weights. The taste of the cathions also varies with variations in their atomic weights. When the taste of the various ions is compared with their motility as expressed in their speed of migration under the influence of the electric current, a number of instances are found that seem to indicate that the greater the motility of the ion, the more pronounced is its taste; other results, however, go to prove that the intensity of the taste is determined not only by the readiness with which the ion can penetrate to the nerve endings, but also by its reaction with the protoplasm of the same. The character of such a reaction is necessarily dependent upon the character of the ion.

By the comparative study of solutions having common chemical properties, the characteristics of the individual ions are determined. Let us consider two hypothetical, equimolecular solutions. B^+A^- and B^+C^-. If the A- and C- ions are tasteless, then the taste of the solution is due to the B- ions. If the B- ions have a certain taste, then a difference in the taste of the two solutions must be due to a difference between the ions A- and C-. Comparing solutions which contain a common anion but different cathions of known characteristics, we approximate the characteristics of the anion. When the substance under consideration is not entirely dissociated, we have to take into consideration the taste of the undissociated molecules.

Garrey[22] studied the effects of ions upon the aggregation of a flagellate infusorian, Chilomonas. A complete analogy exists between the effects of certain ions and the effects of other stimuli (light, galvanic current, etc.) in the formation of gatherings of these infusoria. Garrey was able to distinguish two causes for the infusorial gatherings: first, chemokinesis; second, positive chemotropism. By the first term is understood a reaction of the infusorian to sudden changes in the concentration of the chemical; by the second, an orientation of the organism which causes it to move toward the centre of diffusion of certain chemicals. Chilomonas exhibits chemokinesis toward the hydroxides of lithium, sodium, potassium, calcium, strontium, and barium; and toward the acids, HCl, HNO_3, and H_2SO_4. The effects are due in the first case to the OH- ions, and in the second to the H- ions. That we are dealing with ion effects is proven by the fact that different alkalies containing the same number of OH- ions in equal amounts of water produce equal effects upon the organism. Similarly, equal amounts of H- ions at the same concentration produce equal effects.

HCl of a certain concentration is able to cause gatherings of infusoria. Since an equimolecular NaCl solution is unable to do the same, it must be the H- ions which determine the activity of the acid. The same reasoning applied to equimolecular NaOH and NaCl shows that the OH- ions are the effective agents in the production of the infusorial gatherings.

Toward the carbonates of the alkali metals and alkali earths, Chilomonas is chemokinetic, and the effect is probably due to the OH- ions* formed secondarily, and in part, perhaps, to CO_3- ions or undissociated molecules. NH_4OH owes its chemokinetic properties to the OH- ions, plus the NH_4- ions or NH_3OH molecules. The effects of CO_2 are similar to those of the other weak inorganic acids. The chemokinetic reactions of Chilomonas to the inorganic salts of iron, zinc, copper, mercury, and silver are due to the metallic ions.

From a study of the data furnished by Miquel's[24] table on the efficiency of antiseptics, Kahlenberg and True[4] concluded that just as the poisonous action of solutions of electrolytes upon the roots of lupines is dependent upon the ions contained in them, so also is their bactericidal power. In the hands of Paul and Krönig[25] this theory was fully substantiated. They exposed for varying lengths of time cultures of the staphylococcus pyogenes aureus, and the spores of anthrax, dried on properly prepared Bohemian garnets, to equimolecular antiseptic solutions. The garnets being of equal size served as a means of obtaining approximately equal numbers of bacteria to expose to a given germicidal agent. After being washed to remove the antiseptic solutions, the garnets were introduced into tubes of culture media, and the media plated. The number of colonies developing within a certain time after such a process served as an index of the bactericidal power of the electrolyte under consideration.

Equimolecular solutions of mercuric salts arrange themselves, according to their degrees of electrolytic dissociation, in the following order: $HgCl_2$, $HgBr_2$, $Hg(CNS)_2$, HgI_2, $HgCy_2$. When arranged according to their bactericidal powers, the order is the same. This power, then, is dependent upon the number of Hg- ions contained in the solution. $HgCl_2$, which contains the largest number, has the strongest germicidal action, while $HgCy_2$, which is least dissociated, has the feeblest. So weak is the action of the cyanide that, at a concentration four times that of a bichloride solution capable of destroying all cocci and spores, it permits the development of several thousand colonies of the staphylococcus and many colonies of the anthrax bacillus.

If K- ions are substituted for the Hg- ions by the substitution of KCl for $HgCl_2$ in the antiseptic solution, the germicidal powers of the solution decrease —another fact which proves that the Hg- ion is the specific germicide. If now, instead of substituting KCl for $HgCl_2$, KCl be merely added to a definite solution of $HgCl_2$ of known germicidal power, the disinfecting power of the solution is diminished. The same is true of the chlorides of other metals. This

* A normal eight-hundredth solution. A normal solution is a gram-molecular solution. The denominator indicates how many times the normal solution has been diluted.

* All salts of strong bases with weak acids are decomposed by water. The reaction may be thus expressed: $Na_2CO_3 + HOH = NaOH + NaHCO_3$. The NaOH gives rise to the OH- ions.

occurs either because the electrolytic dissociation, and, in consequence, the number of Hg- ions, is diminished through the presence in the solution of another electrolyte, or because of the formation of the less dissociable double salt, $NaHgCl_2$.

Behring[26] states that the bactericidal power of a mercurial is dependent upon the amount of mercury contained in it, and is independent of the nature of the compound. That this is not true is conclusively proven in the above experiments.

The toxic effects of silver and gold salts are similarly found to be dependent upon the Ag- and the Au- ions. The Pt- ions have only slight germicidal properties. That it is the ions which are thus effective is proved by the fact that $HgCl_2$ or $AgNO_3$ in absolute alcohol and ether (solvents in which but slight dissociation occurs) have no deleterious effect upon anthrax spores. Experiments with other metallic compounds show that when the metal of a metallic salt exists as part of a complex ion, the number of metallic ions is decreased, and the germicidal properties of the solution are correspondingly diminished. The toxic action of a metallic salt depends not alone upon the action of the metal ions, the cathions, but also upon the anions, for two equimolecular, equally dissociated solutions, containing a common metallic ion may show different bactericidal powers. Other experiments go to show that the undissociated molecules also play a part.

In normal solutions, or in concentrations greater than this, the strong acids act not only according to the concentration of the H- ions, but also according to the specific properties of the anions. The more dilute solutions of the strong acids act according to their degree of dissociation. The hydroxides of potassium, sodium, and lithium, all of which dissociate to about the same degree, have the same germicidal powers. To the less degree of dissociation of the hydroxide of ammonium is to be attributed its lesser power of disinfection. The oxidizing agents, nitric, chromic, chloric, and manganic acids, have oxidizing and germicidal properties dependent upon their degrees of dissociation.

The work of Scheurlen and Spiro[29] corroborates the results obtained by Paul and Krönig.

*

It will be noted that but little has been said in the preceding pages of dissociable organic compounds, such as organic acids and salts. This is because dissociated organic substances do not follow in their physiological and pathological manifestations the ordinary laws of ionization. Richards[20] found in comparing the sour taste of tartaric, citric, and acetic acids with that of inorganic acids, that the former are more sour than one would expect from the number of free H- ions in their solutions. Kahlenberg[21] observed that acetic acid is about four times as sour as one would expect from the dissociation theory. From the study of a series of acid sodium salts of dibasic organic acids, the same author[27] finds the attempt to explain the sour taste of these substances on the theory of electrolytic dissociation unsatisfactory.

Garrey[22] found the reaction of Chilomonas to a $\frac{n}{1000}$ lactic acid the same as that to a $\frac{n}{1000}$ hydrochloric acid solution. It can at once be seen that we do not here deal with the effect of H- ions alone, as at 19° C. a lactic acid solution of this concentration contains less than a third as many H- ions as the HCl solution. The effects of organic acids, then, do not bear a definite relation to the number of free H- ions that they contain.

The experiments in which Loeb showed that the addition of small amounts of an acid to the physiological salt solution in which a muscle is immersed, causes the muscle to take up a considerable amount of water have already been cited. For inorganic acids the amount of water taken up by equal masses of muscle in a given time is the same, if the solution contains an equal number of H- ions in the unit volume. The organic acids, however, act more strongly, and cause a greater absorption of water than would be expected from the degree of their dissociation.

These apparent exceptions to the general behavior of electrolytes demand an explanation. Loeb[6] suggests that the organic acids are transformed inside the muscle into products which undergo a greater degree of dissociation. A somewhat similar explanation is offered by Ostwald[28] when he writes: "The phenomena observed here [referring to Loeb's experiments on muscles] would be explained if we assume that the muscle cells contain the neutral salts of an acid of medium strength, the anion of which reacts with the H- ion of the organic acid." Thus would be formed an acid capable of greater dissociation and consequently greater chemical activity. Garrey is inclined to believe that similar transformations explain the behavior of Chilomonas toward organic compounds, and it is possible that the exceptions which organic compounds offer to taste reactions may also be cleared up on this assumption.

*

The theory of ionization offers a new field for investigation in the realm of medicine. Its application to the problems of physics and chemistry has elucidated many obscure points. In the solution of the problems of medicine it will yield yet greater results. In the preceding pages an attempt has been made to give some of the evidences which show that in dealing with the action of dilute solutions of inorganic substances we are dealing with the action of their constituent ions. This fact is ever to be borne in mind when we consider physiological, pathological, and pharmacological problems which involve the presence of inorganic substances.

Post-Operative Suppression of Urine.—Morphine in gr. $\frac{1}{8}$ dose every four hours.—CHITWORTH.

CREOSOTE IN PNEUMONIA: A RÉSUMÉ.[1]

By I. L. VAN ZANDT, M.D.,

FORT WORTH, TEXAS.

JANUARY 7, 1894, on account of indications of fermentation in the alimentary canal, I gave a patient, forty-eight hours sick with pneumonia, one drop of creosote every three hours. This was added to my ordinary prescription. I was surprised, on my return the next day, to find the temperature slightly subnormal and other symptoms correspondingly improved. The dose was reduced; the temperature went up. Again I gave a larger dose, and the next day dismissed my patient.

I was so impressed by this observation that I began then, and have continued to this day, prescribing creosote in all cases of pneumonia.

In June, 1898, I read a paper on the subject before the North Texas Medical Association. This was received by some with incredulity, they citing the fact that "all authorities" (whatever that may mean) said that pneumonia was a self-limited disease, and must run its course. Others were willing to make a trial on my report, reinforced by that of several gentlemen present, who had adopted the treatment at my suggestion.

Quite a number of those present, and others who read the published paper, have reported satisfactory results.

In my former paper I mentioned that there was some unevenness as to results in different cases, some yielding in twenty-four to forty-eight hours, others continuing a week or more. I suggested that difference in the infecting micro-organism might account for this unevenness, favoring the idea that the pneumococcic-infected were most amenable to the treatment. This seems to have a probable corroboration in the reports of some others, written and verbal; but the absolute corroboration can be had only when the clinician and microscopist unite in the investigation.

My original prescription was ammonium salicylate gr. viiss., creosote gtt. i., syrup ʒ i., every three hours. In some cases the creosote alone was given. Latterly I have given creosote carbonate gr. (or ♏) viiss., emulsified with acacia. Others give larger doses with possibly better results and no harm.

During all this time I have had cases in which the fever was gone in from twenty-four to forty-eight hours, and I am now somewhat disappointed if my patient is not ready for dismissal by the third or fourth day. In cases which persist longer there is generally an amelioration of symptoms, and the coming of an appetite, to which I was formerly a stranger in pneumonic cases. There is generally a gradual decline in the fever, with only slight moisture of the skin, a critical sweat being rare.

Another thing I, as well as others, have found, is that if the medicine is discontinued as soon as the fever has ceased, there will likely be a recurrence of all the symptoms. Hence I continue the medicine at longer intervals for two or three days after subsidence of the fever.

This recurrence of the fever in lobar pneumonia is a strong argument in favor of the improvement being due to the medicine, for, according to Austin Flint, in lobar pneumonia "relapse never occurs."

The mortality of pneumonia is, as given by Tyson, lobar 20 to 40 per cent., lobular 30 to 50 per cent.; Osler, lobar 20 to 25 per cent., lobular 30 to 50 per cent.; Delafield, lobar 12 to 34 per cent.; Anders, lobar 15 to 25 per cent., lobular 25 to 50 per cent.; average of all, 22 to 39 per cent.

In these seven years I can now recall only four fatal cases of pneumonia in my practice. Two of these were under my care from the beginning of the attack: one following grippe, the other a measles case in most unsanitary surroundings. The other two patients were turned over to me in desperate condition: one sick a week, the other two weeks. In the earlier part of this time I think I lost two or three babies. I treated sixteen cases last winter, with no fatality; dismissing four on the second, five on the third, one each on the fourth, fifth, sixth, seventh, eighth, and two on the tenth days.

Within a year or two after my first observations I saw that some French writer was recommending creosote for bronchopneumonia. In the fall of 1898 "The Doctor's Factotum" contained an extract from the London *Lancet*, reporting twenty-six cases of pneumonia treated with creosote, without a death, of much shorter duration, and with a better recovery than usual. Creosote was not given early in these cases.

Prof. Andrew H. Smith, of New York, in the *Medical News*, November, 1899, after citing several writers and his own experience, goes so far as to recommend that family physicians keep their patrons provided with carbonate of creosote or one of the salicylates, preferably the former, as being better tolerated by the patient, so that in case of indications of an attack of pneumonia (pain in the side with chill), he may take the drug at once and probably prevent the development of an attack.

Dr. J. A. Gracey in the *Charlotte Medical Journal*, December, 1899, says: "The treatment of pneumonia by the administration of creosote was first brought to the notice of the writer by a paper read by Dr. Van Zandt, of Fort Worth, Tex., at a meeting of the North Texas Medical Association. . . . My method is to give either drop doses of creosote every two hours, or ♏ x. or xv. of creosote carbonate in some simple menstruum. When given early in the attack the results are almost specific; the temperature subsides, the respiration improves, and in the course of twenty-four hours the condition of our patient is so much improved that we sometimes doubt our diagnosis.

"In later stages the results, while not so brilliant, are yet very satisfactory. The cough, pain, and temperature subside, the character of the sputum is changed, and recovery is hastened. And not only in pneumonia do we get such good results, but in acute bronchitis as well.

"The method is worthy of trial, and one has only to use it to be convinced of its merits. Of course, the strength of the patient must be supported, the secretions and excretions attended to; and I am satisfied that we have in the creosote treatment as near a specific for the trouble as is known to-day.

"At the pediatric congress held in Marseilles in 1898, Dr. Cassouté, physician-in-chief to the Marseilles hospitals, gave a brief preliminary notice of his new method for the treatment of pulmonary affections. The method consists in the continuous administration of fairly large doses of creosote carbonate. In most cases a typical fall of temperature occurred during the first twenty-four hours of treatment; and if the creosote carbonate was continued for a sufficiently long period of time the apyrexia was a permanent one. The temperature curve rose again, however, when the drug was discontinued, before the auscultatory signs had disappeared. Relapses and sequelæ, so frequently seen under other methods, were entirely absent."

Dr. Charles F. Stokes, United States navy, in the *Brooklyn Medical Journal*, August, 1900, says: "I have employed it in several cases with excellent results. . . . Early treatment offers most satisfactory results."

Dr. J. W. Frieser, of Vienna, in the *Aerztliche Central-Zeitung* says: "The treatment of acute inflammatory affections of the respiratory passages with the drug has yielded entirely satisfactory and even brilliant results in my hands. Both clinician and practical physician are fully aware that we formerly pos-

[1] Read before the Central Texas Medical Association.

sessed no remedy that was even half-way satisfactory in its action upon pneumonic disease process. Our entire therapeutic armamentarium was symptomatic and expectant in its nature. . . . But it is an unmistakable advance if experience teaches us the employment of a remedy which has an influence on the disease process itself, and possibly upon the specific organisms that cause it. The favorable effects of creosote carbonate upon the various forms of pneumonia have been noticed by others as well as by me; and they are undoubtedly due to antiseptic and antibacterial action of creosote, which, in the form of the carbonate, can be introduced into the body in sufficient quantity and in innocuous shape. . . . Besides this it has a favorable influence on the heart and the patient's general condition; it causes, as I have often noticed, a rapid fall of temperature and retrogression of the local symptoms. The gastro-intestinal canal is in no way injured by its use. . . . In some cases the inflammatory processes in the lungs got well with such extreme rapidity that the method might be called an abortive treatment. The temperature rapidly sank to normal, the general condition noticeably improved, the tongue cleaned and became moist, and the appetite returned. . . . Equally favorable results were obtained from the use of creosote in five cases of acute bronchitis. The action of the drug was reliable and the recovery of the patient rapid."

Dr. Wilhelm Meitner, in the *Medicinisch-chirurgisches Centralblatt*, June 22, 1900, says: "The most important effect of the creosote treatment is the surprising fall of temperature a few hours after its administration is begun; it becomes normal in two days or sooner. With this the general condition improves, the pulse becomes better, the breathing quieter; the cough is lessened, thirst ceases, and the dryness of the mouth and lips disappears. Then the tongue cleans, the appetite returns, the entire course of the disease is cut short, and convalescence is about abrogated. Under creosote treatment I have never seen that weakness followed by a slow convalescence, which is the rule even in typical one-week pneumonias, under the usual medication.

"Some cases run so rapid a course under the treatment that it is hardly possible to give their history. A child falls suddenly sick, with a temperature of 102.2° or more, and the pulmonary signs of an acute catarrh. After two or three doses of creosote carbonate in the next four to six hours, it is better; in twenty-four hours the fever and physical signs are gone; on the second day the child cannot be kept in bed. An adult with marked coryza suddenly begins to cough violently; the first large dose of creosote mitigates his cough, and in twenty-four hours it has disappeared. To me, at all events, the favorable influence of creosote carbonate in acute pulmonary diseases seems absolutely demonstrated. I am sure that its action is the quicker the earlier its administration is begun; that it is harmless and well borne in the doses that I employ; and that no other treatment at all is required in the class of cases under consideration."

Dr. M. Eberson, in the *Aerztliche Central-Zeitung*, July 7, 1900, says: "It has been customary, after the diagnosis of a pneumonia has been made, to admit the presence of a severe disease, requiring five to nine days to run its course. Creosotal von Heyden is now prescribed by the attendant. When he returns on the next day there is no trace of fever. The child is playing, it is hungry, bright, and does not cough. Percussion and auscultation show no signs of inflammation. The physician, and more especially the parents, begin to have a doubt of the diagnosis. But now comes the interesting part! Treatment is stopped; and behold! on the next day the subjective and objective symptoms of pneumonia are again present.

"Two things may therefore be claimed for the creosote treatment. In the first place, it cuts short the disease in a most remarkable manner. In the next, and more important, it causes complete resolution of the disease focus, so that the sequelæ, more especially after catarrhal pneumonia, will not be as important in the future as they have been regarded to be in the past. Nor does it seem to me to be unimportant, considering the bacillary origin of pneumonia, that the sputum and excreta are voided disinfected, so that the contagiousness is reduced to a minimum.

"It is incontestable that the creosote treatment of pneumonia is a very important advance in practical medicine."

Now, with this array of testimony re-enforcing my own observations for the last seven years, I trust that the members of this association will not consider me oversanguine when I express the opinion that the use of creosote or carbonate of creosote in the treatment of acute pulmonary inflammations is one of the greatest life-saving discoveries of the century just ended.

ORCHID CULTURE IN ITS RELATION TO A NEW, IMPROVED, AND COMPLETELY EFFECTIVE METHOD OF DISINFECTION.

By J. M. W. KITCHEN, M.D.,

EAST ORANGE, N. J.

With the exception of a few of my personal friends, I imagine that not a single reader of the Medical Record could guess as to the relation suggested in my heading. There are a few doctors of medicine who grow orchids, and they would be likely to come nearer to solving the problem than others; for they know what the orchid grower has to contend with in the way of bacteria and insects pests—the conditions needed to successful orchid growing being unusually favorable to the existence of a long list of foes that do not bother the grower of ordinary flowering plants—pests which are exceedingly difficult and expensive to keep in subjection, and which have been, and are now, the principal obstacle to profitable commercial orchid culture.

A few years ago, when my honored parents passed into the unknown, and accommodatingly left to their heirs the accumulation of prudential lives, I took the opportunity to shake off the dust and respiratory-irritating influences of New York City life, and emigrated westward twelve miles, when I struck a land elevated two hundred feet above sea level; blessed with an atmosphere that gave me complete immunity from bronchial irritation, and a chance to study the mosquito at least nine months in the year. The average New York City medico may not believe what physical benefits may be secured by a removal from the city this short distance into Essex County, N. J. He may not realize that in various other districts of the northern part of the hilly half of the State, there are sanatoria equal in value to the far-distant resorts to which he sends his patients for climatic advantages. Still such advantages do exist. There are other advantages to be gained by such an emigration. I enjoy, for example, the privilege of living on a civilized street, yet have a considerable area of back land on which one may gratify himself in all sorts of horticultural and floricultural indulgences. I took to orchids somewhat extensively, and was very soon in conflict with the foe before mentioned, and determined to conquer or die. I am alive to tell the tale, and the "bugs" are not. I have not made a fortune in orchid culture; but, because of one thing leading to another, I have invented a combustion regulator that is really a marvel, and, also without intending to do a

great act, have evolved an idea that will be of value to the world, which, with the editor's permission, I will relate. The object I had in view was to find an easy and economical means of controlling insect and other forms of life in my orchid houses. Incidentally, allow me to state that bacteria of various kinds, which have been a source of great loss to me, have been overcome by means of a sufficiency of fresh air, and in furnishing other conditions inducing the greatest normal vigor of existence in the various species under my care; just the same, it will be noted, as in managing the cases of human beings attacked by the lower forms of life. The problem of the insects was complicated by the fact that in the potting-soil used in orchid culture a very fibrous material has to be used—usually fibrous peat and sphagnum moss, in the interstices of which the pests could hide and in a measure protect themselves from such insecticidal means as were brought to bear on them. These hiding pests had to be reached, and they had to be killed without marked injury to the host plants—a problem it will be seen not unlike that presented in medical practice in many instances. In solving this problem I have spent several years, and have learned many things of interest to science. I have found that the lower forms of life can be destroyed by feeding them with articles inimical to life; by bringing matters in contact with them which destroy by corrosive action and by a hardening of the tissues; by causing them to absorb paralyzers of function, and by repeatedly subjecting them to influences of a depressive nature that prevent reproduction, though they may not be immediately fatal to the individual. I have brought to bear on the enemy nearly every poison known to science, and have repeatedly nearly killed myself instead of the foe. I have discovered that any agency that will injure the protoplasm of an insect or a germ, will also injure the protoplasm of a higher animal or of a plant. In applying life-destroying agencies to germs or insects, it is more a matter of methods than of destructive agents. With plants as with men, we must apply destructive agents to the parasites without doing harm to the hosts. To a certain degree the peculiarities of idiosyncrasy may be made available. It is very astonishing that some poisons which are very dangerous to man have little or no effect on certain insects. The converse is true in a lesser degree. With this fact in mind, may we not take increased hope that something may be found which will destroy various inimical bacteria in the human body, without fatal results to man? Of all the poisons experimented with, I have found hydrocyanic acid gas the most deadly to all forms of life. It is also the most dangerous to handle. Several times I have unknowingly inhaled this gas, and nearly lost my life each time. The noticeable effects occur with the quickness of a lightning stroke. One may cautiously inhale a slight amount of an attenuated mixture of the gas and air, with only a rather agreeable general glow of the body and a slight vertigo. But if there is a sufficient dose inhaled, one is suddenly stricken with almost complete respiratory paralysis, blindness, and other paralytic conditions. A sufficiency of this gas will destroy all forms of life in plants or animals. The next most powerful poison is nicotine. The nearer its approach, in use, to chemical purity, the greater is its proportionate effect. So far as I can judge from my experiments, a smoker does not absorb much if any of pure nicotine. In my efforts to disassociate nicotine from the tobacco plant, I found that, in the process of burning, practically all of the nicotine was decomposed into other and less deadly products. It is astonishing how far a very little chemically pure nicotine will go in destroying life. It seems to do so almost entirely by paralyzing function.
